Ear-Nose-Throat: Difficulty in breathing; frequent "sore-throat"; "lump" in neck; nose bleed easily; impairment of hearing in both ears to complete deafness in one ear; "head colds," "running nose"; pain in ear-canal as also back of ear, occasional "ear discharge"; excess wax; dryness of skin of ears with scaliness.

Mouth: Receding, tender, swollen gums; bleed easily; looseness of teeth, multiple cavities; soreness of tongue.

Eyes: "Blood shot"; itchy, scaly and swollen lids; visional disturbances in his distance, near or both; blurring and double vision; partial to complete blindness in one or other eye; "shooting" pains occasionally in eyeballs; overflow of tear fluid; slight "bulging" of eye-balls.

Respiratory: Shortness of breath; frequent "chest colds" accompanied by coughing spells; chest pains, radiating, spasmodic and sharp along rib border accompanied by numerous "itching" blisters; sometimes dull ache between shoulders.

Gastro-intestinal: Indigestion, "heart-burn," "sour" stomach, "bloated" feeling in stomach, belching, (excessive gas formation); pain in gall bladder region; constipation, attacks of looseness of stools; sharp pains, spasmodic in times on sides of abdomen, occasional nausea and vomiting; rectal discharge, itch and sometimes sharp pain during bowel movement. Appetite not good, a few could go all day with only two or three cups of plain coffee or tea.

Genito-Urinary: Sharp pains over kidney areas radiating toward bladder; frequent, burning, painful urination; increased desire to urinate; blood in urine, passing of "stones" or "sand."

Extremities: Cold, numb and tingling sensations; mild to marked weakness in legs; "cramps" in muscles of legs and feet; difficult walking; swollen ankles; pus discharge from "ulcer in callous of foot" and from "ulcer of leg in region of ankle," accompanied by slight pain; varicose veins; sharp pains radiating from hip to knee and foot and also from shoulder to hands; sharp pains in one or both shoulder joints following any physical effort; twitching with marked tremor of arms, hands, legs and feet with "loss of muscle power" at infrequent intervals; general ache; painful joints of hands with swelling, aggravated by movements; "cold" hands and feet.

Skin: Dry; itch (general and local); scaly; pallor; red (small) spots distributed over legs and hips; "bruises" easily following any blow, resulting in bluish discoloration. Marked bluish discoloration of skin of feet; yellowish tinge to skin of face and body; easily blanching of feet and hands; marked itch between toes and "soles" of feet; large "blister" on big toe.

Neurological: Depressed; irritable; weakness—mild to extreme; "crying spells"; "suicidal intention"; insomnia; "dizzy spells"; easily fatigue; mental disturbances; paralysis on one side of body; fainting spells.

Cardio-vascular: Shortness of breath; palpitation, "heart misses a beat"; heart "pain"; body feels "bloated" or "swollen."

Gyn: Pelvic pain; scanty menses; irregular menstruation; still birth, miscarriage, bloody vaginal discharge; "lump" in breasts.

Of this group 36 or (42%) of the patients were taking insulin and 49 or (56%) of the patients were not.

SUMMARY OF OUR OBSERVATIONS

1. All the patients in the group suffered from symptoms other than diabetes. The disturbances involved the gastro-intestinal, genito-urinary, gynecological and cardiovascular systems as well as the visual field and oral, neurological, skin, joints and endocrine glands. Forty-two or (48.2%) of the patients were

obese; 5.4% suffered from gangrene; 3.5% from malignancy.

2. All the diabetics in our series were still ignorant of the true nature of their condition—a factor in the causation of increased diabetic complications and mortality.

3. All the diabetics were on restricted diets.

4. None of the patients in our group adhered to their prescribed diets.

5. The substitution of artificial foods such as gluten bread, diabetic muffins and the like "diabetic food" for some of the vitamin-rich natural foods are still advocated by many of the physicians.

6. Avitaminosis and hypovitaminosis was found in everyone of the patients in our series. These disturbances were not the result of one vitamin, but of several, as amply evidenced by the patient's dietary history, symptoms, and physical disturbances.

7. Many physicians adjust insulin dosage to the carbohydrate allowance only, disregarding proteins, fats, vitamins and other elements of diet.

8. Forty-two per cent of the diabetics were on insulin and fifty-eight per cent were not.

9. Many physicians advocate insulin first, when blood sugar is slightly elevated without complications, in preference to a basal or maintenance diet, when diet alone could reduce the blood sugar.

10. There was a marked correlation in vitamin-deficiency diets to rise in incidence of diabetes, diabetic complications or concurrent diseases.

11. There was no correlation in over-eating to rise in incidence of diabetes or concurrent diseases.

These observations inspired us to determine the effect of correcting the diet of these patients. Burnett (26) explains the cause of the development of disease deficiencies as the failure of normal nutrient substances to unite with the protoplasm of the cells to maintain them in a healthy state; such a disorder often manifesting itself in diametrically opposite structural changes in the tissues. He describes cases to substantiate his theory—pellagra in which there is a general atrophy of the cells; and in vitamin A deficiency in animals and patients with pernicious anemia in which there is a hyperplasia of abnormal cells in the bone marrow. Smith (27) is of the opinion that the various pathological conditions are simply the result of disordered nutrition through lack of certain essentials or unfavorable proportions of substances which depend upon one another for their utilizations or some metabolic disturbance which prevents the assimilation and utilization, of the available materials. Salter (28) emphasizes two fundamental concepts for which accessory food-substance play in metabolic processes. (1) Discovery of pro-vitamin's material in foodstuffs which may be transformed by the animal recipient into vitamins. (2) To those who care for the sick is the idea of "conditioned" vitamin deficiency occurring with a normal diet. In the face of abnormal conditions, it is no longer considered safe to place too great a trust in normal, average figures for vitamins requirement.

To insure proper utilization of the food, we examined all patients carefully to determine whether they were suffering from any physical disturbances which would interfere with the proper metabolism of the food. If such a disturbance was found, we tried to correct it so as to prevent what Castle (29) termed "conditioned deficiency" because a normal intake of vitamin is insufficient due to the condition of the patient. In correcting these diet deficiencies we advised natural foods in preference to artificial concentrates or special vitamin preparations. The report of the Council on Pharmacy and Chemistry (30) states, "It has apparently been forgotten that no necessity has been found for administering preparations containing complex combinations for effective maintenance of health when a well balanced diet is taken"—"when a specific vitamin in its natural state is administered utilization in the normal body is adjusted according to a nicely regulated mechanism."

Another factor which must be considered is the cost and the availability of such special preparations as vitamin concentrates or "diabetic foods." The costs of especially prepared diabetic foods or concentrates are too expensive for common use by persons of somewhat limited means. "Artificial substitutes for ordinary foods are not to be favored; it is much better for the diabetic patient to learn how to plan his diet with foods in common use and readily available" (31). Goddard, Sandifur and Beatty (32) found that special proprietary, diabetic and reducing foods varied in percentage composition. They found that some furnished no calories but merely bulk; others contained less carbohydrate or less available fat than the corresponding ordinary foods, still others contained as much potential sugar as ordinary food. Shohl (33) demonstrated that rats on normal diet retained three times as much calcium and five times as much phosphorous as those on rachitogemic diets.

In supplying natural food we stressed a variety of vegetables, fruits, meat, cheese and milk. No special diabetic preparations were advocated. All the patients were placed upon a high carbohydrate diet between 100-180 grams per day, proteins 60-80 grams, fats 80-120 grams, and we advocated vitamin-rich foods so that the patient would receive the various vitamins to alleviate any signs or symptoms which apparently were caused by their deficiency. In view of the fact that none of the ordinary foods with the exception of butter and egg-yolk contain any appreciable amount of vitamin D, we found that the main source would be milk vitaminized by irradiation or the milk of cows which had been fed irradiated yeast. Wherever possible we advocated sufficient exposure to sunlight in addition to other hygienic measures as exercise, daily walks, care of the eyes, mouth, bowels and fluid intake. In prescribing the diets to the clinic patients, we had to consider the cost, advocating adequate amounts of foods which were marketed at a price the patients could afford. These diets were prepared by our chief dietitian, Miss Joyce O'Neill.

Foods (34) tabulated below were advocated in any quantity the patient desired without consideration of

carbohydrate content. In the table below is inserted their vitamin (18, 20) content.

TABLE II

FOODS	A	B	C	G
Asparagus	Variable	++	+++ ?	+++ ?
Celery	— to +	++	++	·
Cucumber	— to +	+	++ ?	·
Cranberries	+	—	++	—
Green Beets	+	+	+	+
Green dandelion	++	++	+	++
Lemons	+	++	+++	++
Lettuce	+ to ++	++	++	++
Limes	—	·	++	·
Mushrooms	— to +	++	—	++
Okra	++	++	·	·
Radishes	— to +	++	++	·
Rhubarb	·	·	+	·
Spinach	+++	+	++	+++

These foods which were found to be rich in vitamins and minerals, but poor in carbohydrate, served to satisfy the appetite. In reasonable amounts in the diet these foods gave bulk to the intestinal residues and helped to relieve constipation. We have found that the patients allowed such foods showed no increase of blood sugar but rather as improvement in their physical condition. The insulin patients were given insulin within 15-20 minutes after meals and not before (35).

The effects of the correction of the diet deficiency were noted by the changes in the symptoms and signs, blood chemistry, insulin dosages, weight and the patient's mental aspect. The duration of the dietary treatment varied from 10 days to 14 months.

RESULTS OF NATURAL FOOD VITAMIN DIET

1. All the patients in the group showed better adherence to the natural food diet.

2. All showed improvement and reduction in their symptomatology of the gynecological, cardiovascular, gastro-intestinal, neurological and genito-urinary systems as also of the joints, oral, nose, throat, and visual fields. Patients with partial or complete deafness, blindness due to cataract, retinitis, optic atrophy or neuritis showed no improvement of the affected part but a diminution of concurrent disturbances and better metabolic control. Such disturbances as sciatica, neuritis, generalized ache or pain, fatigue, weakness, headache, constipation, insomnia, irritability, mental disturbance, tingling, numbness, epigastric discomfort, muscle pain, toxic erythema, acute dermatitis, perforating ulcer of foot and obesity were almost completely alleviated, an improvement resulting in better metabolic equilibrium. Three cases of dermatitis gangrenosa healed without complications.

3. Of three patients of the group who suffered from kidney "colic," two of them after passing numerous "stones or concretions" periodically for 3-4 months showed no more pain, renal or bladder disturbances. The remaining one passed no "stones" but showed relief of "pain" within ten (10) days to the extent of discarding a kidney belt that she had worn for the past four and one-half years.

4. Sixty per cent (60%) of the insulin group were able to discontinue insulin and maintain normal blood sugars. Of the remaining 40 per cent taking insulin half were able to reduce their insulin dosage, though of the other half, the insulin dosage was increased. Of the remaining group (49) who entered our department and who had never been on insulin therapy, 1.6% were given insulin in order to maintain blood sugar optimum for their age.

5. There was less fluctuation of blood sugar in the great majority.

6. All the members in the group took on a more pleasant outlook toward life.

7. Whether the vitamins were supplied in sufficient quantity or not the fact remains that the patients in the group showed marked metabolic improvement on the natural food vitamin diet.

CONCLUSIONS

1. Physicians should interest themselves more in the science of nutrition so as to be better able to detect and treat any diet deficiency.

2. We strongly advocate a more detailed study of the patient's diet history as well as of the symptomatology.

3. The diabetic's diet should consist of natural foods, rich in the essential vitamins and other elements, since such diet will more often result in greater adherence by the patient to his instructions. The following advantages will be obtained:

(1) Better co-operation of patient with doctor,
(2) Less complications, symptoms or physical disturbances,
(3) Less insulin,
(4) Better metabolic equilibrium,
(5) Better outlook upon life,
(6) Prolongation of the span of usefulness,
(7) Greater resistance to infection,
(8) Avoidance of avitaminosis and hypovitaminosis,
(9) More energy.

4. In trying to alleviate physical disturbances due to vitamin deficiency we advocate the administration of natural foods containing the essential elements. Perhaps vitamins depend upon each other for their normal effect within the body in the same manner as the endocrine glands.

5. Diets consisting of a variety of natural foods such as vegetables, fruits, milk and its products, meat and cereals in the prescribed proportions with hygienic measures as sunshine, fresh air and exercise, will result in little need to worry for vitamin deficiency in diabetes.

Vitamin B Complex Therapy in Chronic Arthritis*

By

CHAS. LEROY STEINBERG, M.D.
ROCHESTER, NEW YORK

AN atonic bowel associated with chronic arthritis has been found by several clinicians. These clinicians differ somewhat in their remedy. Whereas Fletcher and Graham (1) and Gatewood, et al (2) recommend vitamin B along with restricted carbohydrates as a means to bring about a normal bowel, Pemberton and Pierce (3) on the other hand have been able to return the bowel to a normal contour with the aid of low carbohydrate—low calorie diets which were obviously not very rich in vitamin B. Haft (4) has suggested that any chronic disease may cause the same intestinal abnormalities that are found in chronic arthritis. This thought suggests that treatment of the chronic disease itself should correct the bowel abnormality.

Most research workers have shown that diets deficient in vitamin B cause an atonic bowel. McCarrison (5) fed monkeys food which was first autoclaved and a ballooning of the large bowel occurred. Fletcher (6) could demonstrate atrophy and metaplastic changes in the mucous membrane of the rat's colon by means of a diet high in carbohydrate and low in vitamin B_1. He was able to demonstrate atony of the colon in the rat by diets low in vitamin B. Elsom (7) showed that loss of tone and motility of the gastro-intestinal tract could be brought about in human beings by the administration of diets deficient in vitamin B. McCollum (8) believed that the neurotic element caused by the deficiency of vitamin B in the average American diet was a predisposing element in the etiology of ulcer.

A careful study of the systemic history of the chronic arthritic, omitting the symptoms confined to the joints, shows a marked similarity to that which may be induced by diets deficient in vitamin B.

STRIKING SIMILARITY OF SYMPTOMS CAUSED BY DIETS DEFICIENT IN VITAMIN B COMPLEX AND SYSTEMIC SYMPTOMS IN CHRONIC ARTHRITIS

Chronic Arthritis

1. Digestive disturbances
2. Lack of vigor
3. Disturbance of carbohydrate metabolism
4. Weakness
5. Poor appetite
6. Lowered metabolism

Deficient Vitamin B Diet

1. Digestive disturbances
2. Lack of vigor
3. Impairment of tissue respiration
4. Weakness
5. Poor appetite
6. Glandular dysfunction.

The following findings were obtained in a study of the gastro-intestinal history of 118 patients having chronic arthritis. 105 of this group had atrophic arthritis and 13 had hypertrophic arthritis. Gas, constipation, and anorexia were symptoms present in almost the entire group of 118 patients. Occasional diarrhea, heartburn and epigastric pain were present in a few cases. The gastro-intestinal symptoms were associated in most cases with a systemic complaint of weakness or apathy. Duodenal ulcer symptoms corroborated by the finding of a deformed duodenal cap were noted in four patients in the atrophic arthritic series.** Barium enema studies were made on 24 patients of the atrophic group and the most common abnormality noted was spasticity and not atony of the

*From the Department of Medicine, Rochester General Hospital. Submitted September 11, 1936.

**Since this paper was written two more cases of duodenal ulcer associated with chronic arthritis have been encountered.

colon. In fact, the former was found in 79% and the latter in only 4.1% of the 24 patients.

Are the diets of these arthritic patients deficient in the B complex? Hall and Myers (9) found a deficient or borderline deficient general vitamin diet in 50% of the cases of infectious arthritis, 42.5% of the atrophic arthritics, and in 26.7% of the hypertrophic cases. The non-arthritic control group showed a general vitamin deficiency of 33.3%. Brownson and Steinberg (10) found that whereas the average fruit and vegetable intake of the nonarthritic was two and one-third cups per day, the arthritic ate one and one-half cups of fruits and vegetables per day. With this small difference between the arthritic and the nonarthritic, one could hardly surmise that a lack of vitamin B intake was an etiological factor in chronic arthritis. This, however, does not imply that the vitamin B requirement is not greater in the arthritic than the nonarthritic.

The effect of vitamin B on the gastro-intestinal symptomatology was studied in the series of 118 cases of chronic arthritis. The vast majority had the atrophic type of chronic arthritis. 108 patients were given "Vitamin B Complex" in doses of 4 c.c. to 12 c.c. daily. The usual dose was 4 c.c. twice daily. Ten patients received one cake of brewer's yeast daily. Three patients were given 30 c.c. of a live strain of brewer's yeast which was alternated with the "Vitamin B Complex" preparation with practically identical effects. These preparations were successful in alleviating the gastro-intestinal symptoms in over 95% of the cases. Of the nineteen patients in this study who did not have any gastro-intestinal upsets, a mild diarrhea was occasioned in only one case. The cessation of administration of the vitamin B preparations resulted in the return of symptoms in about 50% of the cases. One to three weeks were required to obtain the beneficial effects of the vitamin preparations. All of the cases preferred the palatability of the "Vitamin B Complex" to the other vitamin products.

Further studies were made to determine any incompatibility between vitamin B complex and two other vitamins: A and D. This group included 20 cases of chronic arthritis with marked gastro-intestinal symptoms of gas and constipation. This group included 13 cases of atrophic arthritis, 3 cases of mixed arthritis with the atrophic factor predominating, 2 cases of Marie-Strumpel arthritis, and two cases of hypertrophic arthritis. Vitamin B complex in doses of 8 c.c. to 12 c.c. daily was given to thirteen cases of this group in periods varying from three months to twelve months with complete cessation of the untoward gastro-intestinal symptoms. At the end of this varying period, massive doses of vitamin D, 250,000 to 750,000 units were given daily for periods varying from two to six weeks in ten of the preceding cases with no change in the already improved status of the gastro-intestinal symptomatology. Two cases that had received improvement with the vitamin B complex were also given 18,600 units of vitamin A and 2700 units of vitamin D daily for another three months with no change in the already attained intestinal improvement. In another case the liquid vitamin B complex preparation was replaced with a capsular form and doses of 18,600 units of vitamin A, 2700 units of vitamin D, and 135 Sherman units of B_1 and 30 Sherman units of B_2 were given daily without any change in the improvement attained with the vitamin B complex preparation. Four patients received massive doses of vitamin D (250,000 to 750,000 units) daily at the same time that the vitamin B complex was started in periods varying from two to three months, with the same beneficial pharmacological effect on the gastro-intestinal tract. Three patients received capsules of 18,600 units of A, 2700 units of D, 135 Sherman units of B_1 and 30 Sherman units of B_2 daily without any initial period of the vitamin B complex with identical beneficial gastro-intestinal symptomatology.

COMMENT

The present trend in thought that vitamin B complex increased the tone of the atonic bowel needs modification. This study indicates that vitamin B complex aids in restoring an abnormal bowel tone to a normal status; the vitamin B complex possesses pharmacological value in restoring this tone whether the bowel be atonic or hypertonic. This is an entirely new concept as to its value. The discovery of four cases of duodenal ulcer in four cases of chronic arthritis along with the suggested apparent increased demand for vitamin B complex in the chronic arthritic opens up another possible attack upon the unknown etiology of peptic ulcer.

CONCLUSIONS

1. Spasticity of the colon is commonly associated with chronic atrophic and hypertrophic arthritis.
2. There is no vitamin B deficiency which accounts for the gastro-intestinal symptomatology present in the cases of chronic arthritis reported in this paper.
3. There probably is an increased demand for vitamin B complex in the chronic arthritic.
4. Four cases of duodenal ulcer are reported in a relatively small number of cases of chronic arthritis.
5. There is no pharmacological incompatibility amongst vitamins A, B, or D as regards the gastro-intestinal effect in the group reported in this paper.
6. In a study of 118 cases of chronic arthritis of which 99 had gastro-intestinal symptoms, it was found that the vitamin B complex is of adjunct value in the treatment of chronic arthritis.

The author takes this opportunity to thank Dr. E. A. Sharp, Director Department of Experimental Medicine, Parke, Davis & Co., for his assistance in supplying the vitamin preparations for this study.

He also expresses his gratitude to Dr. L. R. Lingman, Director Department of Radiology, Rochester Central hospital for the radiographic interpretations.

SECTION IV—*Roentgenology*

The Roentgen Diagnosis of Acute Intestinal Obstruction

By

JACOB BUCKSTEIN, M.D.*
NEW YORK, NEW YORK
and
LEON MICHAELS, M.D.
SAN FRANCISCO, CALIF.

IT is surprising that so objective and reliable a criterion as the roentgen method for the diagnosis of acute intestinal obstruction, should not have attained the universal recognition among clinicians that the procedure deserves.

As far back as 1911, Schwarz (1) of Vienna, described four cases in which by the oral administration of bismuth, he established the diagnosis of obstruction of the small intestine. He demonstrated the following points: First, dilatation of the loops of small intestine, approaching the colon in size; second, exaggeration of Kerkrings folds; third, fluid levels capped by gas in the dilated small bowel in the erect position; fourth, delay in the motor function of the small intestine.

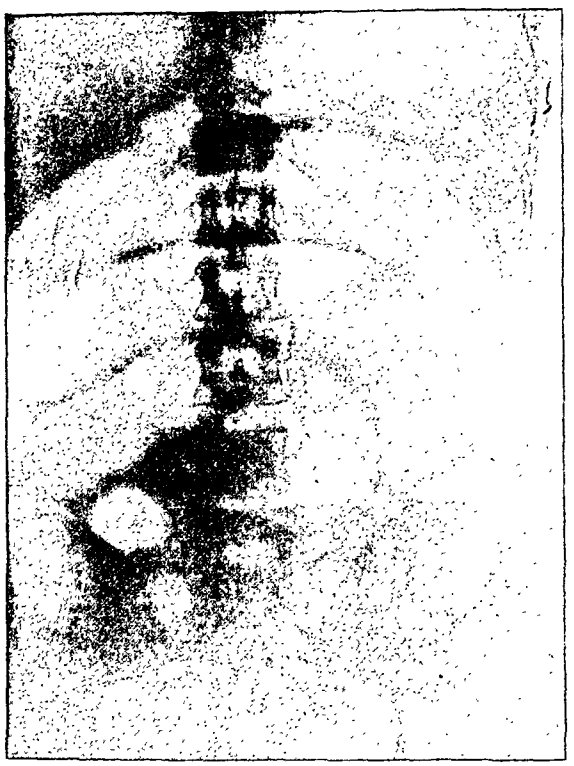

Fig. 1. Note the marked dilatation of the coils of small intestine and the arrangement like a spiral spring. No fluid levels are noted because the film was taken in the prone position.

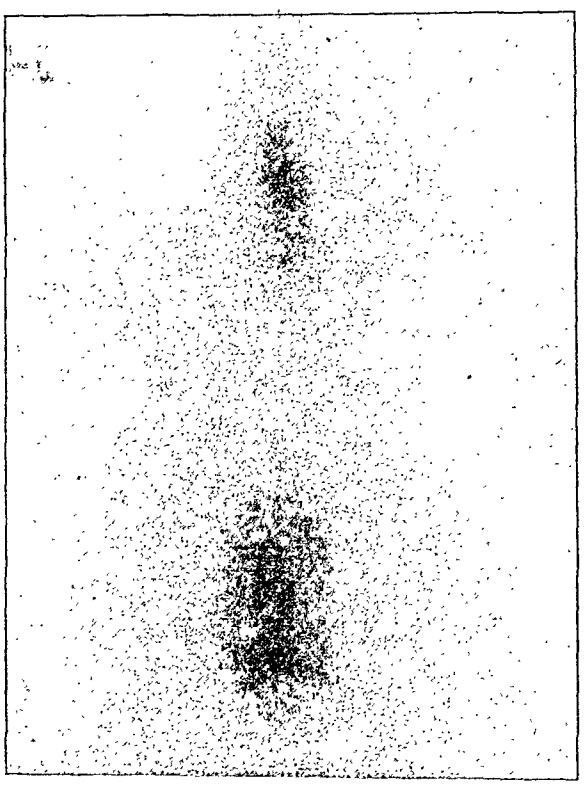

Fig. 2. Note the numerous fluid levels throughout the abdomen, surmounted by gas. This is the classical appearance in acute obstruction of the small intestine when the film is taken in the erect position.

These classical findings were corroborated in 1913 by the famous Stierlin (2) who made one valuable additional observation. In a child four years old who developed evidence of intestinal obstruction one week

*Visiting Roentgenologist (Alimentary Tract Division) Bellevue Hospital, New York City.
Submitted August 24, 1936.

Fig. 3. Note the marked dilatation of the loops of small intestine. The folds of Kerkring are prominently shown.

Fig. 5. Another example of acute intestinal obstruction showing gas capped fluid levels.

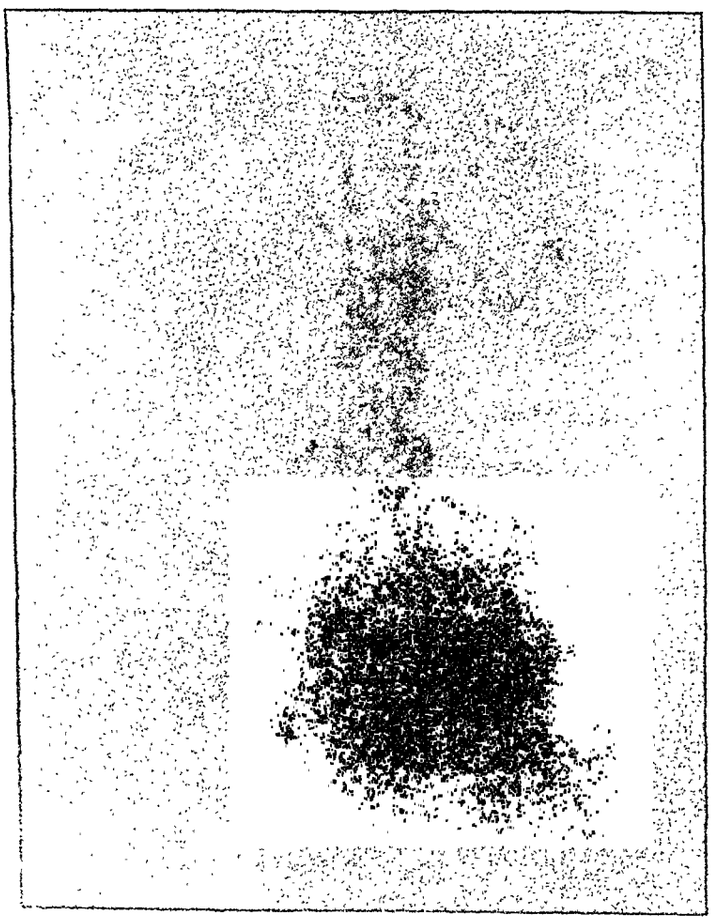

Fig. 4. Marked dilatation of the small intestine with unusual prominence of the folds of Kerkring.

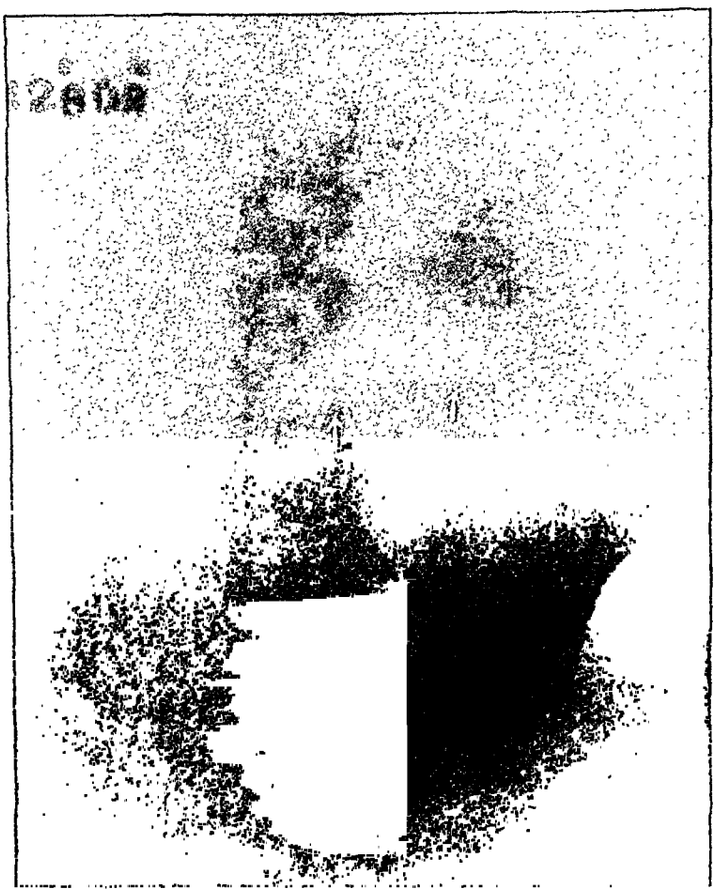

Fig. 6. This roentgenogram taken in the erect position exhibits distention of the small bowel, fluid levels surmounted by air caps, and prominence of Kerkring's folds.

Fig. 7. Obstructive Malignant Lesion of the Sigmoid. The flat plate shows a complete arrest of the gas in the colon at side of new growth.

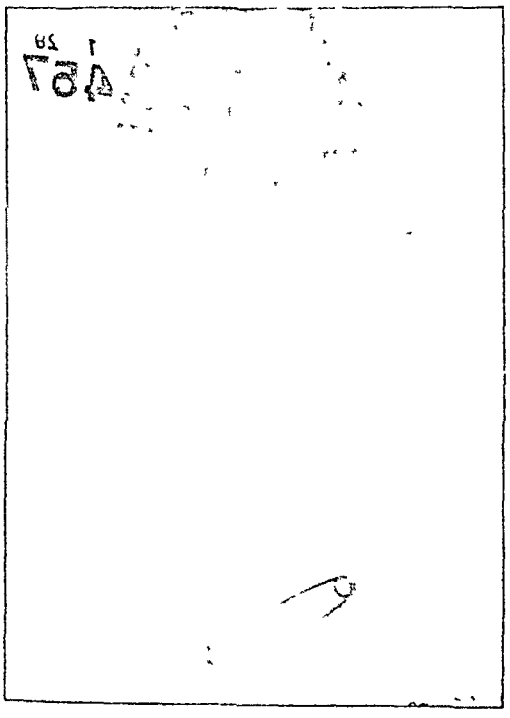

Fig 8. Congenital Atresia of the Transverse Colon in a Newborn Infant (verified at autopsy). Note the unusual prominence of the gas distended loops of small intestine. Film taken in the erect position.

after an appendectomy the roentgenogram showed the characteristic evidence of marked dilatation of the loops of small intestine, although no bismuth was administered by mouth. The child died and at autopsy adhesions and abscess formation were found to have caused the intestinal obstruction.

Much water has pased under the bridge since these two memorable and fundamental contributions were made to the diagnosis of obstruction of the small intestine and a fairly large literature has arisen since then, emphasizing the great significance of the method.

Notable among these are the contributions of Novack (3), Czyhlarz and Selka (4), and particularly that of Assmann (5) who in 1913 also described the dilatation of the small intestine with fluid levels surmounted by gas bubbles as seen roentgenologically even prior to the administration of bismuth by mouth.

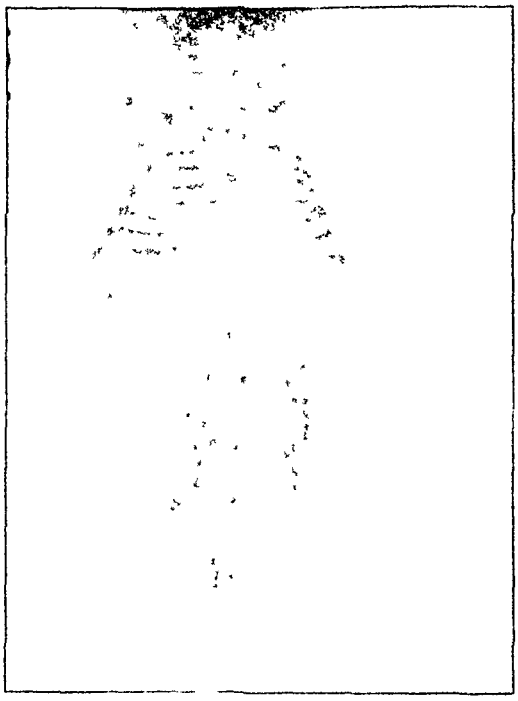

Fig. 9. (Same Case as Fig. 8). Appearance after barium enema. Complete arrest of the barium at the mid portion of the transverse colon.

It is this ability to roentgenologically recognize the presence of obstruction of the small intestine, without the administration of an opaque medium by mouth, that was later emphasized by Marcuse (6), Case (7, 8), Kloiber (9), Ginzburg (10), Wangensteen (11), Rendich (12), and others Kloiber showed that a characteristic roentgen picture could be obtained within three hours after the onset of clinical symptoms eventuating in intestinal obstruction.

In this country, Case particularly did pioneer work in establishing the validity of the roentgen diagnosis of acute intestinal obstruction.

The rapidity with which characteristic roentgen evidence appears after the onset of obstruction, is of course of enormous importance, because of the rapidly increasing mortality with every hour of delay in surgical intervention.

It is interesting therefore to note that in experimentally produced simple obstruction in the dog Ochsner (13), showed that gas distention of the small bowel occurred as early as one hour later and fluid levels in three hours. Hibbard, Swenson and Levin (14), were able to show gas shadows as early as one and one-half hours after ligation of the superior mesenteric artery in dogs, and the development of fluid levels in four hours. It is this ability to roentgenologically demonstrate evidence of intestinal obstruction, long before the clinical picture has become clear, that constitutes the life saving value of this simple diagnostic procedure. The film should preferably be taken in the erect posture when possible, to show fluid levels, although films in the prone and lateral positions are also of considerable diagnostic value.

Not only is the administration of barium by mouth unnecessary, but it may in some cases do considerable harm. Particularly noteworthy is the observation of Smithies (15) who described four cases in which an acute intestinal obstruction was converted into a perforation after the ingestion of barium.

Reflex ileus may infrequently produce the roentgen appearance of acute obstruction of the small intestine. Among such possible causes, may be ureteral colic and acute pancreatitis or a twisted ovarian cyst. Assmann many years ago (1913) described the intestinal contraction of lead colic as capable of producing fluid levels in the roentgenogram. Also he described fluid levels in tetany and in tuberculous peritonitis without actual ileus. The differentiation between dynamic and adynamic ileus by the roentgen method is in my opinion impossible. Clinically such differentiation may be possible by auscultation. The 'ominously silent abdomen' of Deaver may indicate the presence of an ileus of adynamic origin.

A small amount of gas may sometimes be normally present in the small intestine of the adult, and even fluid levels scattered throughout the alimentary tract may be noted after catharsis (Rendich).

The classical roentgen picture, however, rarely gives rise to any doubt. Where the evidence is of a borderline nature, examination at frequent intervals may clear up the difficulty.

Interpreted in the light of the clinical history, the flat film, taken prone, laterally and particularly in the erect position, furnishes objective evidence of enormous importance as a life saving measure in establishing the early diagnosis of acute intestinal obstruction.

The following are reproductions of films chosen to exhibit the roentgen characteristics in operatively proven cases, which justified the diagnosis of acute intestinal obstruction.

What Drug Best Kills Hookworms?

By

CLAYTON LANE, M.D.*

EALING, LONDON, ENGLAND

IN the interests of the individual and the community, treatment of hookworm infection in man should aim at complete deworming (1). Those who hold that fewer than twenty-five (or a hundred) worms are harmless to the individual, do so on scant evidence (Lane, 1932). In public health, the inference (Molloy, 1933) that a community of 618 souls should view with a quiet mind the fouling of their precincts by 1,383,350 hookworm eggs *every day* is unacceptable.

THE TESTS

Worm loads are commonly estimated by egg counts. This is doubly unwise. First, the rate of ovipositing

*Editorial Editor, "Helminthology," Tropical Diseases Bulletin, London, England.

Submitted September 15, 1936.

varies with species, age and number of worms; with diet, drink and drugs taken by the host and probably with the presence of other worms. Second, egg counts are no true measure of worm loads, for different techniques using the same stirred stool may give quite different totals.

The most erratic in my hands has been Stoll's, hence my suggestion that all using it should check it in their own hands. For this, Ahmann and Bristol (1933) report two essentials—a training period of fifty slides; the counting and averaging of at least four slides from each suspension. Little of the world's helmintholo-gical literature escapes collection by the Bureau of Hygiene and Tropical Diseases. I call to mind no paper reporting that this care has been taken in converting egg numbers into worm loads. As judged by controls, the most accurate egg-counting technique in my hands is D.C.F.F. (2). It has been decried by those who have altered it in essentials, transferred the odium to the original, and let the matter rest there. On present evidence, it is the most accurate means of determining the egg-content of feces; diagnostic techniques must then be graded by it. So tested, the best of them is D.C.F. It will disclose a single normally ovipositing *Ancylostoma duodenale* or *Necator americanus*. By its use Kendrick (1934) found the life-span of *A. duodenale* longer by one to three years and of *N. americanus* by four years than shown by Stoll's method. Only then, by tests for deworming can anthelminthic drugs adequately be graded. This is now a rapid matter, for the area needing examination in a herded D.C.F. preparation is about 9 sq.mm., and with a twelve-tube centrifuge, four men can make and examine these preparations at the rate of 250,000 yearly.

THE ANTHELMINTHIC DRUGS

Since hookworms rarely kill directly there is no justification for putting efficiency of anthelminthics before their safety.

Thymol. Its optimum dosage is grs. 60. Its crystals, if packed, coalesce into a solid unabsorbed mass unless particulation is effected, as by grinding it fine with at least an equal part of, say, milk sugar or sodium bicarbonate. It is on particulation that its efficiency depends. Thus, Washburn and Payne in Trinidad had, after two optimum treatments, a deworming rate of 12.6 from plain and one of 49.1 from particulated thymol. British Guiana and Ceylon confirmed this; and from the extent of films examined, all these figures must have been close to accuracy. Giles (1890) held that pouring an alcoholic solution of thymol into some eight times its volume of water and shaking vigorously gave a particulated and potent suspension; the physical result is a very fine floccular particulation, though when not so shaken, the tiny globules which first form, coalesce, and by evaporation give rise to large floating plates. Its potency after such precipitation still awaits proper testing. Caius and Mhaskar (1919) showed that after particulation by grinding, no thymol was found in the feces or in the worms passed, nor was most of the loss accounted for by known derivatives in the urine. On analogy with quinine and emetine, I suggest that something formed from thymol by the host is the true vermicide. At least, fear of dangerous absorption induced by alcohol seems ill-founded, as Bozzolo too felt. The postmortem appearances of all cases I have been able to collect (1932) differ, except for two brothers dosed together, and reappearing after an absence in the woods to die of acute gastro-enteritis. If all died from thymol this is perhaps unique. Howard (1919) reported a million cases in the United States with no death when instructions had been carried out, and Ashford (3) 1,600,000 in Porto Rico with no death. My own 60,000 administrations without anxiety are relatively unimportant. These facts are insufficiently weighed by those who dub my conclusions as old-fashioned and reactionary. There is still that prejudice for the new which struck Paul of Tarsus in the Athenians some 1900 years ago; there is also that preference for proof among careful physicians with patients' lives in their hands. It makes for safety that thymol is apt to produce "drunkenness" in a dose well below the fatal one. (Foot Note)

Beta naphthol. The minimum lethal dose is 20 grains (Milne, 1933), lower ones are inefficient. Suppression after passage of smoky urine is a marked feature.

Oil of chenopodium. The active and lethal principle, ascaridole, varies from 33 to 98 per cent, the doses fatal to man and worm are close together, and the size of drops, by which it has been constantly measured, vary from 18 to 70 to the c.c. It is commonly given without knowledge and report of its ascaridole content. It seems never to have been checked by tests for deworming when the ascaridole content was known, so that after hundreds of thousands of administrations its real worth is unknown. It has killed a number of subjects, but perhaps not an adult man in a dose of 0.8 c.c. of ascaridole. It may cause permanent deafness.

Carbon tetrachloride. The minimum lethal dose, habitually exceeded and relatively inert, is 1.5 c.c. (Bais, 1924). It produces liver necrosis greatest round the hepatic vein, regeneration taking place from cells surviving about the portal vein; but ankylostomiasis itself may produce degeneration about the portal vein (Ashford and King, 1907) and presumably defeat regeneration. Excess of blood guanidine is a grave risk, added to by calcium deficiency, and it is among persons so suffering that hookworm campaigns are usually undertaken (Ashford, 1933). Instinctive calcium hunger is perhaps shown by Dr. J. W. Lindsay (3), for, in Paraguay, poor country children often scrape off and eat the whitewash from dispensary walls, which may have to be rewhitened several times a week. Concommitant ascaris infection is a marked danger. Yet the drug is often given in "herd fashion" without microscopic confirmation of hookworm infection or exclusion of any dangerous factor. With Ashford's experience of 1,600,000 doses of thymol with no death, compare nineteen deaths in the same number of doses of carbon tetrachloride in Egypt (Tomb and Helmy, 1933) and the ambiguous statement of Khalil (Hassan and Salah, 1935) that seven or eight cases of "poisoning" are reported yearly by the Parquet in Egypt.

Chenopodium and Carbon Tetrachloride. Tests are few, and the oil's ascaridole content unstated in all.

Foot Note: To avoid the poisonous effects of thymol administered in effective anthelmintic dose, 30 to 60 grains, we have exhibited always after the patient has been on fat-free diet for a minimum of 36 hours prior to the taking of the drug and keeping fat—as cream, butter, etc.—out of the diet for twenty-four hours after the drug has been taken. Black coffee prevents circulatory weakness. A saline purge is given six hours after the last dose of drug. *Editor.*

Soper (1924) with respective doses of 0.6 and 1.8 c.c. had a seeming deworming rate of 35 per cent to Willis's technique, but further treatment showed that it had been only 10%. Maplestone and Mukerji (1929) with respective doses of 1 and 3 c.c. had a deworming rate of 26.3 to D.C.F.

Ascaridole and carbon tetrachloride. With respective doses of 0.75 and 1 c.c. (Pessôa, 1924), the real cure rate was unknown, but two of forty-eight treated became so ill that thirteen refused a second controlling treatment.

Ecuador experience. Soper (1935) wrote regarding the suspected recrudescence of yellow fever in South America, that after many postmortem "viscerotomies" on these cases, pathologists disagreed on the significance of the lesions; but against yellow fever were the facts that none occurred in the cities, immunity tests on children were negative, and clinical histories were inconclusive; yet all save one had received anthelminthic treatment of an unstated kind. The pertinent experience of J. W. Lindsay in Paraguay is that after treatment by oil of chenopodium or carbon tetrachloride or both in standard doses according to age, given by native orderlies not always under professional control there have been deaths in children, and in adults, ruined health with enlarged liver and jaundice (3). At present grave responsibility rests on all using or advising this treatment.

Tetrachlorethylene. No death has yet been reported though Kendrick (1929) was very anxious in one of 15 administrations when 3 c.c. were given to a man of 10 stone. Lambert wrote (1933) "I report . . . . . over 46,000 treatments with tetrachlorethylene without death and without untoward symptoms." His dosage was 15 to 60 minims, but the results of treatment were unstated, presumably unknown. Maplestone and Mukerji (1929) had to D.C.F., 15 per cent of deworming in forty patients with a dose of 3 c.c. Garrison (1934) had, to a brine floatation method, 93 per cent of cures among institutional children with a dose of 3 c.c. for a child of ten, but the inadequacy of the best of these methods had been noted above.

Tetrachlorethylene and oil of chenopodium. With respective doses of 3 and 1 c.c. Maplestone and Mukerji (1929) had a 28.2 per cent deworming rate to D.C.F., and when tetrachlorethylene was increased to 4 c.c. (1933) one of 62 per cent. The ascaridole content was noted in neither. Without reporting controls, they advise that the drugs should be given shaken up in 2 oz. of magnesium sulphate solution to produce subdivision and enhance potency. Presumably the latter fails, for Darling, Barber and Hacker (1920) had better results with plain than emulsified chenopodium oil; and as to the former, in my observation tetrachlorethylene precipitates visibly in ten seconds, and almost completely in sixty seconds after this shaking.

Hexylresorcinol. Molloy's dosage was 1.05 gram for all over eleven years old; two treatments gave to Stoll's technique a deworming rate of 19.4 per cent. It must have been less, for Maplestone and Mukerji (1929) had eight apparent cures to Stoll's method after tetrachlorethylene treatment, but D.C.F. showed that only one was dewormed. The drug causes great erosion of the mucosa, which encapsulation happily shifts out of a mother's sight unless a perverse child chews a capsule.

CONCLUSIONS

For individual, community, or medical man investigating anthelminthics, complete deworming is the only stable aim. The deadline of anthelmintics is urged against this aim. But, before reaching the dangerous stage, thymol and tetrachlorethylene, like alcohol, give warning which makes for safety. Though it was probably these timely symptoms which led to the disuse of thymol, they are now being used to recommend tetrachlorethylene. The evidence for the safety of thymol is more solid than for any other drugs, so the objection to deworming by it is poorly based; its efficiency depends upon particulation, but the effect of the finest particulation has never been measured. Tetrachlorethylene merits controlled tests on a proper scale. The cheapness of beta-naphthol is no balance to its risks. Oil of chenopodium must not be given without knowledge of its ascaridole content, seeing how near together are the optimum and minimum lethal doses; its production of deafness is not negligible. Carbon tetrachloride is liable to be either highly extrolled or dropped when it kills; to look before giving it for the factors known to make for deadliness is constantly neglected; with oil of chenopodium it lies under grave suspicion of ruining health and causing death in South America with simulation of yellow fever. Hexylresorcinol "also ran," not having fulfilled the expectations of its introducers.

There is urgent need for the carrying through by experienced medical men of controlled comparative tests on an adequate scale to determine on the only stable basis—deworming—what anthelmintic is the safest and most effective in the expulsion of hookworm. Such stable knowledge is long overdue.

The Spastic Colon Diet

By

EDWARD E. CORNWALL, M.D., F.A.C.P.
BROOKLYN, NEW YORK

THE spastic colon demands special dietetic consideration. One is for a smooth diet. Alvarez has particularly described and emphasized this indication. The smoothness in this connection means generally low content of cellulose in the food stuffs. Another special indication has reference to the susceptibility of food stuffs to putrefactive bacterial action; which susceptibility, as well as the absorption of putrefactive products from the intestine, is favored by the abnormal functioning of the colon. These two indications, *viz,* for smoothness and for inferior susceptibility to putrefactive bacterial action, particularly guide in the selection of food stuffs for the spastic colon diet.

For supplying the protein ration in this diet, *milk* is the preferred food. Milk is free from indigestible residue and is protected to a certain extent from the action of putrefactive bacteria by its dissolved carbohydrate, lactose, which is readily fermented by the lactic acid bacteria. (Acidification makes for inhibition of putrefaction). By milk is meant not only milk, but also modification of milk and preparations of milk and of its separated constitutents.

Milk may be mixed with water, cereal preparations, strained fresh fruit juices and strained decoctions of vegetables. Milk and barley water, strained milk and oatmeal gruel (made with cooked oatmeal porridge which is cooked a second time in the milk and strained), milk and cooked cream of wheat and milk with the cream of wheat cooked in it, are examples of cereal mixtures.

A serviceable mixture with fresh fruit juice is made with strained orange juice, the latter being sufficient in quantity to curdle the milk in fine flakes on agitation.

Useful mixtures with strained cooked vegetables are the pureed milk soups, as cream of celery, tomato, corn, carrot, etc.

Modifications of milk produced by fermentation used in this diet are those made with lactic acid producing bacteria and yeast—the sour milks and koumyss.

Predigested milk — peptonized and pancreatized — serves a useful purpose in some instances.

Of the *cheeses,* cream and cottage cheese are the most suitable, although rennin-made cheese, as American Cheddar, Parmesan and Edam cheese may sometimes be used if properly comminuted and made smooth, as in cheese sauce baked with macaroni.

Eggs, although belonging in the distinctly putrefactive class of food stuffs, have a place in this diet because of their freedom from insoluble residue and their easy digestibility.

Cereals, selected with due regard to their cellulose content, have an important place in the dietetic management of spastic colitis. Their use in combination with milk has been referred to. Cream of wheat and rice deprived of its hulls, are comparatively smooth when boiled. White bread twenty-four or more hours old, especially if toasted, can be used by many patients. Oatmeal in the form of the strained gruel is generally acceptable, if the straining is effective.

The *sugars,* as they occur naturally in fruits and milk, are acceptable, also to a certain extent, honey; cane sugar is generally to be avoided.

Of the *fat foods,* olive oil, butter and cream have the highest rating. Some patients tolerate butter more readily than they do cream, which seems, of the two, to be the more often productive of digestive disturbances. Olive oil taken late in the evening, the patient lying on the right side for a short time immediately following its ingestion in order to facilitate its passage from the stomach into the intestine, may be useful as a laxative.

Among the acceptable *fruits* in this diet the first place would seem to belong to the banana (1). The edible portion of the fully ripe banana contains (2): Water, 75.6%; Protein, 1.3%; Fat, 0.6%; Carbohydrate, (Dextrose, 4.5, Levulose, 3.5, Sucrose, 11.9, Starch, 1.2) 21.1%; Ash, 0.8%; Crude fiber, 0.6%.

In respect to their mineral content, bananas are "relatively rich in phosphorus, magnesium, potassium and sodium, and also contain copper and manganese." They are particularly rich in their content of vitamin A; and they contain fair quantities of vitamins B, C and G. They are exceptionally well protected from bacterial invasion while in the market by their thick capsule. These qualities of the banana, *viz,* its high nutritive value (the average sized banana supplies 100 calories), its easy digestibility and its low content of insoluble residue, especially recommend it for the spastic colon diet. Its "roughage," moreover, which is comparatively smooth"—Bogart refers to its "soft texture,"—can act as a gentle laxative without producing much irritation to the spastic colon.

But the banana must be fully ripe for this diet. Ripeness in indicated by the dark spots which appear on its capsule; also it must be prepared in a special manner. After being peeled, the "fuzz" must be scraped off. The fruit must be masticated thoroughly to a pulp, or, better, mashed before being eaten, in order to preclude the possibility of lumps being carried from the stomach and small intestine into the colon.

The banana may be eaten plain as above described, or in mixtures. A serviceable mixture is made with cream cheese, in the proportions of two parts of the banana to one of the cream cheese, or in other proportions. Six ounces of this two-to-one mixture supply protein, 14 grams; fat, 16 grams; carbohydrate, 26 grams, and have a fuel value of 310 calories. In-

Submitted August 2, 1936.

stead of cream cheese, cottage cheese may be used in this mixture if a lower caloric value is desired.

The banana pulp also may be mixed with milk, cream, or strained fresh orange, grape-fruit or pine-apple juice; or the fruit juice may be added to the banana and cream cheese mixture.

In addition to banana, among fruit food stuffs in this diet, strained juice of fresh orange, grapefruit and pineapple, pure, or mixed with water, are acceptable. The pulp of baked apple, or even stewed apple, may be well borne by some patients.

The vegetables allowed in the management of the spastic colon must be "smooth," which means, in the case of the leafy and stalky vegetables, the green seeds and seed pods, the gourds, bulbs and roots, that they require straining after they have been cooked.

Of the *salad vegetables*, raw tomato, which has had the skin and seeds removed, generally is acceptable.

Water should be given in good quantity, but not in excessive quantity.

Table salt should be given in ordinary rations, but not in excess.

The *beverages* containing caffein generally are contraindicated.

Spices are forbidden.

Animal flesh usually should be avoided, but to certain patients, some of it may be allowed. The flesh foods containing small amounts of fibrous tissue are to be preferred, as for example the breast of chicken. Also, fishes, those with low fat content which are of easy digestibility, are to be preferred. There is a place in this diet, although only an occasional one, for clear meat broths as stimulants to appetites and digestion.

All food in this diet should be taken neither very hot nor very cold.

The following diet lists are constructed in accordance with the facts and principles above mentioned. They lend themselves easily to modifications to suit particular needs.

SPASTIC COLON—DIET I

(Protein, 85 gms. Fat, 110 gms. Carbohydrate, 215 gms. Calories, 2200).

Breakfast

Moist cooked cream of wheat, 120 gms. (4 oz.).
Toasted white bread, 30 gms. (1 oz.).
Egg, soft boiled or poached, 1.
Butter, 15 gms. (½ oz.).

At 10 a. m. (or with breakfast)

Milk, 180 gms. (6 oz.), mixed with strained orange juice, 60 gms. (2 oz.); or milk or junket, 240 gms. (8 oz.).

Dinner

Strained milk-vegetable soup, *viz:* cream of celery, carrot, tomato, potato, green pea, onion, oyster plant or spinach, 240 gms. (8 oz.).

Banana, ripe, with "fuzz" scraped off, mashed, 120 gms. (4 oz.), mixed with cream cheese, 60 gms. (2 oz.).

Toasted white bread, 30 gms. (2 oz.).
Moist cooked rice, 120 gms. (4 oz.).
Butter, 15 gms. (½ oz.).

At 4 p. m. The same as at 10 a. m.

Supper

Banana and cream cheese mixture as at dinner.

Strained boiled squash, carrot, spinach, string beans, green peas or lima beans, 180 gms. (6 oz.).

Milk, or milk soup as at dinner, or junket, or buttermilk, 240 gms. (8 oz.).

Tomato, raw, with skin and seeds removed, 130 gms. (4 oz.).

Toasted white bread, 30 gms. (1 oz.).

Butter, 15 gms. (½ oz.).

SPASTIC COLON—DIET II

(Protein, 68 gms. Fat, 77 gms. Carbohydrate, 166 gms. Calories, 1600).

Breakfast

Banana mixture, as in *Spastic Colon—Diet I*, 180 gms. (6 oz.).

Milk and oatmeal gruel, made with oatmeal porridge cooked a second time in four times its quantity of milk, and strained, 240 gms. (8 oz.).

At 10 a. m.

Milk and orange mixture, as in *Spastic Colon—Diet I*, or milk or junket, 240 gms. (8 oz.).

Dinner

Banana and cream cheese mixture as at breakfast.

Milk, 120 gms. (4 oz.), mixed with cream, 60 gms. (2 oz.), and barley water, 60 gms. (2 oz.).

At 4 p. m.

The same as at 10 a. m.

Supper

Banana and cream cheese mixture as at breakfast.

Milk soup, as in *Spastic Colon—Diet I*, 240 gms. (8 oz.).

By special order, moist cream of wheat, 180 gms. (6 oz.), may be added to dinner; or an extra feeding of any of the milk combinations may be given at night.

SPASTIC COLON—DIET III

(Protein, 55 gms. Fat, 75 gms. Carbohydrate, 120 gms. Calories, 1380).

At 7 a. m.

Milk or junket or buttermilk, 240 gms. (8 oz.).

At 9 a. m.

Milk and orange juice mixture as in *Spastic Colon—Diet I*, 240 gms. (8 oz.).

At 11 a. m.

Strained milk and oatmeal gruel, as in *Spastic Colon—Diet II*, 240 gms. (8 oz).)

At 1 p. m.

The same as at 9 a. m.

At 3 p. m.

The milk, cream and barley water mixture, as in *Spastic Colon—Diet II*, 240 gms. (8 oz.).

At 5 p. m.

The same as at 9 a. m.

At 7 p. m.

Milk soup, as in *Spastic Colon—Diet I*, 240 gms. (8 oz.).

At 9 p. m.

The same as at 11 a. m.

Substitution of one preparation for another in the above list may be allowed by special order.

An extra feeding of any of the above preparations may be allowed during the night by special order.

Spastic Colon—Diet I is intended for the average ambulant patient. It has a caloric value sufficient for a life of moderate activity. If the patient is confined to bed, the fuel ration may require reduction. If increased physical activity calls for a larger fuel ration, that can be supplied by addition of cereals, butter, olive oil or cream.

If the patient is able to manage a more liberal diet, a small portion of chicken or fish may be substituted for part of the cream cheese; or the number of eggs may be increased. A small portion of clear broth, made with chicken, beef, mutton or clam may be allowed in certain instances.

Substitutions for the purpose of increasing variety and catering to individual tastes and idiosyncrasies easily can be made in accordance with the principles above specified.

An ounce of olive oil, given at night, when the stomach is empty, may have a good laxative effect.

Spastic Colon—Diet II and *Spastic Colon—Diet III* are intended for the more severely ill and bed-fast patients. In most instances it may be well to begin treatment with one of these or a similar diet, and enlarge the diet as the patient's condition improves.

Anal Fissure, Anal Spasm and Anal Stenosis

By

E. A. DANIELS, M.Sc., M.D.
MONTREAL, CANADA

NARROWING of the anal circumference, produced either by muscle spasm, or fibrosis, the result of a lesion of the anal canal, is a condition frequently encountered. Fissure of the anus, anal spasm, and stenosis, although different lesions, are dealt with together in this presentation because their symptomatology is esentially similar and the treatment to be outlined is applicable to all three conditions.

In order to understand the rationale upon which treatment of these lesions is based, it becomes necessary to review the anatomy of the anal canal, especially in the light of more recent knowledge, together with a consideration of the clinical picture produced by anal fissure, anal spasm and anal stenosis.

ANATOMY OF THE ANAL CANAL CONCERNED IN STUDY

The rectum at a point approximately one and a half inches in front of the tip of the coccyx, that is, at the level of the apex of the prostate in the male, and at the apex of the perineal body in the female, bends abruptly backwards, pierces the rectal layer of pelvic fascia, and becomes the anal canal. The anal canal is a narrow slit-like passage possessing in normal people a fair degree of "comfortable" elasticity and distensibility, to the extent that bulky formed stools or the lubricated index finger may be passed without discomfiture to the subject. It is approximately two inches in length in its posterior half and approximately an inch in length in its anterior half. Its walls, when at rest, lie in coaptation. The viscus is directed backwards and downwards from the end of the rectum through the pelvic floor, to open on the exterior as the anus. The anal canal is totally destitute of peritoneum, but is clothed and supported by a prolongation of the rectal layer of the pelvic fascia which it pierces. The muscles which closely surround the anal canal and ano-rectum (together with their nerve supply) are the major factors entering into this presentation and will have to be considered in detail. The musculature of the ano-rectum is considered in this study along with that of the anal canal, and therefore one is here concerned with the terminal two inches (approximate distance of ano-rectum posteriorly) of the alimentary canal.

The anal canal is surrounded by its muscles, the external and internal sphincters and levatores ani, which form its immediate boundaries in both sexes. Laterally there are the ischio-rectal fossa; an important relation, since it is across this fossa from the posterior aspect of the perianal region that the nerves run to supply the anal musculature. Posteriorly one finds the ano-coccygeal body and coccyx. In the male the membranous part of the urethra and the bulb of the urethra are in front of the canal, but on account of the backward inclination of the gut, are separated from it by a mass of fibro-elastic tissue, corresponding to the perineal body of the female. Anteriorly at the top of the anal canal in close relation to the membranous urethra lies the base of the prostate. In the female the anal canal is separated from the vagina anteriorly by a pyramidal fibrous, fatty and muscular mass, the perineal body. The anal canal is lined by squamous epithelium continuous with the skin of the integument, and not by mucous membrane as is sometimes described. The transition to columnar epithelium occurs above the dentate or pectinate line, i.e., above the level of the crypts of Morgagni. The dentate or pectinate line marks the embryologic junction of the proctodeal membrane, where fusion occurred between the proctodeum and hind gut. Extending up from the crypts or pockets of Morgagni are longitudinal folds of mucous membrane, the columns of Morgagni. The crypts of Morgagni are crowned by small papillae, the anal papillae, which may become hypertrophied, and in some instances, become true polypi. The white line of Hilton, referred to in some text books, is not an anatomical entity, but can be seen as a pale circular area, lying below the pectinate line, and actually is the anal intermuscular septum of fascia which separates the subcutaneous part of the external sphincter from the internal sphincter muscle, and lying beneath the skin of the anal canal thus gives a whitish appearance by reflected light.

Musculature of the anal canal and ano-rectum concerned in this study. The basis of conservative treatment in this presentation of anal fissure, anal spasm, and anal fibrosis, is based upon the principle of rest for a fairly prolonged period of time of the muscles of the anal canal and ano-rectum. This follows the axiom of surgical rest, laid down by John Hilton in his Lectures on "Rest and Pain," as long ago as 1860.

Submitted May 14, 1936.

1933 (1). In order to secure this surgical rest by the measures presently to be described, one must consider in detail the anatomy of the musculature of the anal canal and ano-rectum. The Author in securing a prolonged and adequate anaesthesia of this region, has found this objective possible to attain only by observing closely, in his induction technique, the anatomical studies of Milligan and Morgan (2). In 1934 these two workers published their splendid contribution upon the "Surgical Anatomy of the Anal Canal." By following the anatomical landmarks outlined in their paper, the writer has been able, by the technique to be described, in an almost uninterrupted series of cases, to secure very satisfactory results in the treatment by conservative measures of anal fissure and anal stenosis, in cases which hitherto appeared amenable only to radical surgical measures. In the following *resumé* of the anal musculature insofar as it concerns this thesis, the Author in his descriptions has drawn upon the studies and followed the landmarks of Milligan and Morgan (2).

The external sphincter of the anus is divisible into three portions, *i.e.*, it is a trilaminar muscle which together with the puborectalis portion of the levator ani forms a strong muscular cylinder encircling the outer longitudinal muscle of the bowel wall, the internal sphincter ani and below this level the anal canal. In other words the external sphincter of the anus is not the superficial subcutaneous single muscle so often referred to in text books, but is actually a strong muscular cylinder completely encircling the anal canal as high as the ano-rectum, which at its uppermost level joins with a portion of the levator ani to enter into the formation of the ano-rectum. The three components of the sphincter ani externus muscle are: (e) Sphincter ani externus subcutaneous; (2) Sphincter ani externus superficialis; (3) Sphincter ani externus profundus. Fibromuscular septa from the fascia of the longitudinal muscle of the rectum, actually separate and divide off the three portions of the sphincter ani externus. (1) *The sphincter ani externus subcutaneous*, is the most superficial portion of the external sphincter muscle. It is that division of the external sphincter which lies just beneath the skin, and encircles the lowest portion of the anal canal. It is this portion which is often referred to as "the external sphincter," when, actually, it is only its subcutaneous portion and its least important part as far as continence is concerned. It lies in the same plane as the sphincter ani internus, from which it is separated by an annular band of fascia. The sphincter ani externus subcutaneous can be felt just beneath the skin by passing the finger around the anus externally. It may be cut or divided in any direction with impunity. Posteriorly its fibres do not reach the coccyx. It is completely subcutaneous and directly palpable throughout its circumference. (2) *The sphincter ani externus superficialis*, lies above and lateral to the subcutaneous portion of the external sphincter just described. Posteriorly it has an attachment to the coccyx. It lies between the subcutaneous and deep (sphincter ani externus profundus) portions of the external sphincter but on a more lateral plane and surrounds the sphincter ani internus in its lower two-thirds, together with the downward prolongation of the outer longitudinal muscle of the rectum. Anteriorly, its fibres are inserted into the central point of the perineum. (3) The sphincter ani externus profundus, represents the upper and deepest portion of the sphincter ani externus. It is closely fused with the lower part of the puborectalis portion of the levator ani in the posterior half of its circumference. Its lower part is in close contact with the sphincter ani externus superficialis. It surrounds the downward prolongation of the outer longitudinal muscle of the rectum, and the upper part of the sphincter ani internus. The fibres posteriorly are continuous and have no attachment to the coccyx.

The Puborectalis portion of the levator ani guards and enters into the formation of the anorectal ring. It is highly important as regards rectal function and continence. It takes its origin from the back of the symphysis pubis and from the upper layer of the triangular ligament. Its fibres pass downward and backwards around the lower and lateral aspects of the rectum, meeting with fibres from the opposite side behind the anal canal, so forming a powerful loop or girdle, which slings the anorectal junction to the symphysis pubis. None of these fibres reach the coccyx. The lower border of the puborectalis muscle as already mentioned is intimately blended with the sphincter ani externus profundus. Together with this muscle it fuses posteriorly with the downward prolongation of the outer longitudinal muscle of the rectum and is reinforced by the thickened fibres of the inner circular muscle of the rectum, *i.e.*, the sphincter ani internus which it surrounds. The puborectalis lies at the junction of the rectum and anal canal, can be easily identified with the examining finger, and as first pointed out by Milligan and Morgan enters posteriorly into the formation of the important anorectal ring. The anorectal ring in front, therefore, is made up of the deep part of the external sphincter and the outer longitudinal muscle of the rectum, reinforced by the upper fibres of the internal sphincter ani. Anteriorly the puborectalis leaves a U shaped deficiency of the anal canal and does not enter into the formation of the anorectal ring in front. Anteriorly therefore the anal canal is quite short and suspended to the back of the pubic bones by the insertion of the puborectalis. This is an important consideration in the therapy to be outlined presently for anal fissure and anal stenosis. The outer longtitudinal muscle of the rectum takes part in the formation of the anorectal ring. Its fibres posteriorly blend with the puborectalis which lies external to it, and anteriorly with the fibres of the sphincter ani externus profundus.

At the upper end of the anal canal the outer longtitudinal muscle of the rectum becomes fibromuscular, and dips down to ensheath and surround the three divisions of the sphincter ani externus, and has its terminal attachment to the area between the lower border of the sphincter ani internus and the upper border of the subcutaneous part of the external sphincter, i.e., just beneath the skin of the anal canal where a groove can be identified in the living subject, referred to as the anal intermuscular septum.

The sphincter ani internus represents the inner circular muscle coat of the rectum which encircles the whole of the anal canal down to the anal intermuscular septum, i.e., down to the top of the subcutaneous portion of the external sphincter. Its lower border can be felt and identified just below the muco-cutaneous border of the anal canal, about one-fourth or one-half inch from the anal opening. As pointed out by Milligan and Morgan, it does not form a narrow annular band or ring as is so often depicted.

The anorectal ring guards the junction between anal canal and rectum, and is the muscle structure of prime importance guarding continence. The subcutaneous and superficial portions of the external sphincter, part of the internal sphincter, and any of the structures up to this ring, may be cut or sacrificed with impunity, and yet continence will be preserved. Continence is lost with the sacrifice during surgical operations of this important muscle band. The anorectal ring is a composite fibromuscular band composed of: (a) the upper portion of the internal sphincter, (b) the longtitudinal muscle fibres at this level of the rectum, (c) the puborectalis part of the levator ani posteriorly, and (d) the external sphincter ani profundus muscles. Posteriorly the puborectalis enters into the formation of the anorectal ring, but anteriorly it leaves the anal canal to be inserted into the symphysis pubis leaving a U deficiency. Anteriorly the anorectal ring is formed by the internal sphincter, the longtitudinal muscle, and the deep portion of the external sphincter muscle. Anteriorly thorough fusion of the internal and deep external sphincter muscles have occurred to form a composite flat band and identification by palpation is more difficult than posteriorly, because of the presence of the puborectalis in the posterior part of the anorectal ring. The anorectal ring can be easily identified by digital examination of the rectum. It can be recognized by the palpating finger as a circular ridge or shelf between the top of the anal canal and the rectum. Posteriorly this is quite pronounced, because of the inclusion of the puborectalis portion of the levator ani into the musculature of the anorectal ring. Where this inclusion does not occur anteriorly, the anorectal ring is flatter and not so easily recognized by the examining finger. An important consideration in treatment to be shortly outlined is the difference of the levels between the posterior and anterior parts of the anorectal ring. Posteriorly this ring lies at an approximate distance of two inches from the anal opening, roughly the second crease on the volar aspect of the index finger; anteriorly, the distance from the anal opening is approximately one inch, roughly, the first skin crease on the volar aspect of the index finger. This difference of levels is demonstrated in the diagram. In other words the anorectal ring anteriorly lies in a lower plane than the anorectal ring posteriorly. The anorectal ring slopes downwards from the posterior aspect as an inclined plane to the anterior part of the anorectal circumference, and lies at its lowest level at the anterior anorectum. This difference in levels is approximately one inch. This too is an important consideration in operations upon anorectal fistulae; because posteriorly one can sacrifice sphincter muscle with more impunity than one can anteriorly. In the posterior aspect one can cut down on the sphincter muscles to a height of almost two inches in order to lay the fistulous tract open. Anteriorly one very soon reaches the anorectal ring, since it lies at a distance of only one inch from the anal opening. The rectal surgeon has long recognized the danger of incontinence where much sphincter muscle must be sacrificed anteriorly. The anorectal ring is the final and important arbiter as far as continence is concerned. When this is sacrificed in any part of the anal circumference, incontinence is certain to result.

Certain landmarks in the anal and anorectal musculature always can be palpated and recognized. These landmarks have all been described and are enumerated as follows: 1. The subcutaneous part of the external sphincter ani, which lies just beneath the skin at the anal opening and can be felt throughout its circumference; 2. The anal intermuscular septum; 3. The lower border of the internal sphincter ani, felt and recognized just above the groove of the anal inter-

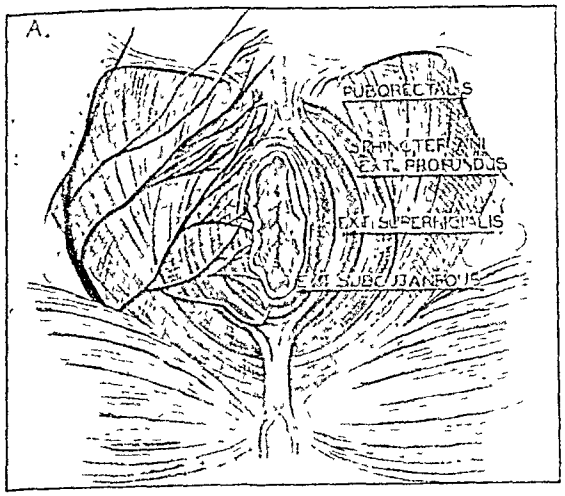

Fig. A. Diagrammatic representation of the musculature of the anal canal and ano-rectum viewed from below. The three portions of the sphincter ani externus muscle are shown in their respective planes. The puborectalis portion of the levator ani muscle can be seen to fuse posteriorly with the deep portion of the sphincter ani externus profundus. Anteriorly the fibres of the puborectalis may be seen leaving the anal canal, and running upwards towards the symphysis. The inferior haemorrhoidal and perineal nerves are shown in position on one side.

muscular septum in the lower part of the anal canal, 4. The anorectal ring; 5. The puborectalis portion of the levatores ani.

NERVE SUPPLY OF THE ANAL MUSCLES AND ANORECTAL RING, CONCERNED IN STUDY

The nerve supply to the muscles of the anal canal and anorectal ring are derived from the third and fourth sacral nerves. The subcutaneous and deep portions of the external sphincter muscle are supplied by the inferior haemorrhoidal nerve which has its origin from the third and fourth sacral nerves. The inferior haemorrhoidal nerve is a comparatively large mixed nerve and one of the three main branches of the pudic nerve which emerges from under cover of the great sacrosciatic ligament. The inferior haemorrhoidal nerve arises in the postero-lateral part of the ischio-rectal fossa and passes forward across the fossa towards the anus. The course that it takes across the ischio-rectal fossa is an important consideration in performing an effective nerve block in the treatment to be outlined. It supplies sensory branches to the skin of the anal canal and peri-anal region and motor branches to the subcutaneous and deep portions of the sphincter ani externus muscle. The superficial portion of the external sphincter muscle is supplied by the large perineal division of the pudic nerve through the fourth sacral. The course of the perineal nerve is like the inferior haemorrhoidal nerve also postero-lateral, but lateral to the latter. The perineal nerve is a mixed nerve, and supplies sensory branches to the skin of the perineum, scrotum or labium majus Some of its sensory fibres anastamose anteriorly with those of the inferior haemorrhoidal nerve to supply the peri-anal skin and that of the anal canal. The sphincter ani internus really the lower continuation of the inner circular muscle of the bowel is supplied with sympathetic nerves in common with the rest of the alimentary tract, but also receives motor nerves through the third and fourth sacral. The levator ani muscle is supplied as well through the third and fourth sacral nerves. Its pelvic portion is supplied by branches from the fourth sacral nerve. The puborectalis is supplied by branches of the internal pudic from the third and fourth sacral nerves. It will be seen from this description that the nerve supply to the muscles of the anus and anorectal ring runs in a forward direction from the postero-lateral perianal aspect, where the nerves lie deep in the subcutaneous fat before they pass inwards to the sphincter muscles. This insures a rich and wholesome motor supply to the posterior and postero-lateral aspects of the muscles which go to make up the anal canal and anorectal musculature. Anteriorly the anal musculature and that of the anorectal ring derive their nerve supply through small terminal filaments of these nerves. As already mentioned the anal musculature is short anteriorly, and in front the puborectalis portion of the levator ani muscle does not join the deep portion of the external sphincter to enter into the formation of the anorectal ring, thus leaving a U shaped deficiency. The puborectalis is fixed to the back of the pubic bones after it leaves the anal canal, acting as a sling to the anterior anorectal ring. The short deficient anal canal and anorectal ring anteriorly devoid of support from the puborectalis, together with its terminal poor nerve supply already pointed out, are factors which render the anal canal quite vulnerable in the anterior part of its circumference. This fact must be recognized in cutting down anterior fistulae, and is further taken advantage of in the conservative treatment to be outlined by the Author for anal fissure, spasm and stenosis.

The skin of the anal canal as far as the pectinate line, is very richly supplied with sensory cerebro-spinal nerves especially from the sensory branches of the inferior haemorrhoidal nerve. Severe pain or burning is therefore a characteristic symptom of any lesion of the anal canal. This by completing the reflex arc produces spasm of the sphincter muscles of the anal canal and anorectal ring. The interpretation, study, and methods of dealing with this clinical picture form the essential substance of this thesis.

CLINICAL STUDY OF THE LESIONS: ANAL FISSURE, ANAL SPASM AND ANAL STENOSIS

Anal fissure may be defined as a break or loss of continuity in the skin of the anal canal, situated as a rule in the posterior aspect of its circumference. It has a strong tendency to become chronic and to resist cure by simple measures. The lesion infrequently occurs in the anterior aspect of the skin of the anal canal. Since the process occurs below the pectinate or dentate line in the anal canal which is lined by squamous epithelium, the lesion therefore is not a one involving the mucosa, as is sometimes erroneously described.

That this break or loss in surface-continuity should most frequently occur in the posterior aspect of the anal canal seems at first difficult to understand. As already pointed out the anal canal is short anteriorly and the anorectal ring lies only a short distance from the anal opening. This renders the anterior circumference of the anal canal quite vulnerable in surgical operations for fistulae, but nevertheless what is present of the anal canal anteriorly is sturdy and formidable. The puborectalis portion of the levator ani further suspends the anal canal to the back of the symphysis pubis, and must be regarded as a protective force. The superficial part of the sphincter ani externus whose fibres fuse in the mid line anteriorly and have a firm insertion into the central point of the perineum, has quite a different arrangement posteriorly. Behind, the fibres decussate to be inserted into the coccyx, forming an angulation as they leave the anal canal to gain this coccygeal insertion. This factor makes for weakness, especially by any distending intra-anal force. The tissues of the perineal body in the female and the fibromuscular body corresponding to this in the male, act as a firm solid support to the anal canal anteriorly and to the area immediately in front of the subcutaneous portion of the external sphincter. This can easily be confirmed by palpating this area. Posteriorly the subcutaneous portion of the external sphincter has no such support by a firm body of fibromuscular tissues, but rather the soft resilient fatty connective tissues between the subcutaneous sphincter and the coccyx. This must be regarded as the important factor rendering the anal canal vulnerable in its posterior circumference, since fissure in ano occurs as a rule posteriorly in the skin of the anal canal overlying the subcutaneous sphincter ani externus. Moreover confirmatory evidence is provided in parous women, in whom anterior fissures are more frequently observed, and who are found to suffer from rupture of the perineal body (rectocele) or thinning out or diastasis of the levatores ani.

The acute fissure manifests itself as a simple loss in surface continuity of the skin of the anal canal, overlying the area of the subcutaneous portion of the external sphincter. There is no induration and very little inflammatory reaction of the surrounding tissues. There is marked spasm of the sphincter muscles of the anal canal up to and including the anorectal ring. Digital examination causes variable degrees of pain and for this reason the anal canal folds in the

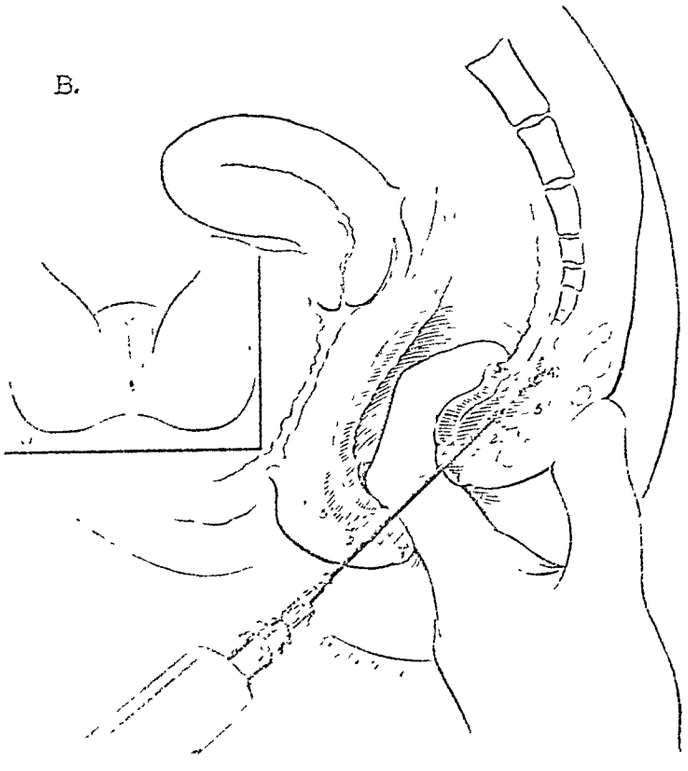

Fig. B. Technique of posterior and postero-lateral anaesthesia. Anaesthetization of the ischio-rectal fossae cannot be demonstrated in this section. The needle is seen traversing the anal and anorectal musculature as high as the anorectal ring. The tip of the finger is hooked around the ridge formed by the anorectal ring, and can be seen to be inserted as far as the second crease on the volar aspect of the digit. (1). Subcutaneous portion of the sphincter ani externus. (2). Superficial portion of the sphincter ani externus. (3). Deep portion of the sphincter ani externus. (4). The puborectalis portion of the levator ani. (5). The anorectal ring, described in text. The sphincter ani internus is shown lying under the finger as a flat and not as an annular muscle.

Fig. B1. The dotted area shows the field of anaesthesia induced by the posterior and postero-lateral technique.

ulcer area, and it takes much patience to retract the anal folds and demonstrate the lesion.

The chronic fissure has induration as its characteristic feature. Its edges are hard and may be in some instances of almost cartilaginous consistency. The anal canal becomes appreciably altered. Whereas in the acute fissure there is spasm of the muscles of the anal canal and anorectal ring, in the chronic fissure there may be actual stenosis of the anal canal. The anal canal is apt to be rigid, fixed and immobile up to and including the anorectal ring. Such is the result of the presence of a chronic, painful irritant, *i.e.*, an insult of long standing. There is an actual fibrosis of the sphincter muscles. This easily may be proved under low spinal anaesthesia, when, in operating upon such patients, there is no relaxation of the sphincter muscles and anal canal. In narrowing of the anal canal whether due to spasm or an actual fibrosis, it becomes impossible for the patient to pass a formed bulky stool of even moderate consistency. Liquifaction of the stool becomes the only alternative in order to effect its passage (3). Fecal impaction in such instances frequently is encountered. Early or late in the course of the ailment, if the acute fissure is not healed with (spontaneous cure rarely occurs) the spasm of the sphincter muscles is replaced by an actual stenosis. One then has a rigid, stenosed, immobile anal canal associated with loss of elasticity and resiliency of its structural components. If the patient be subjected to the painful ordeal of a digital examination, or is subjected to the index finger in the anal canal and the thumb on the perianal area ("bidigital" palpation), the sphincter muscles are felt to be thickened, hypertrophied, non-elastic and firm. The examiner recognizes a "fibrous" feel. This is demonstrable up to and including the anorectal ring, which is thickened and rigid. Because of spasm and hypertrophy, the puborectales are easily identified.

Lawrence Abel, in 1932, described an anatomical entity in the region of the "pecten" in cases of chronic fissure and anal narrowing. He refers to this as the pecten band (4). Abel recognized this band as a circular band of fibrous tissue beneath the pecten of the anal canal, and likened it to a "rubber umbrella" ring. (The "pecten" has been established as that region of the anal canal extending from the anal papillae, *i.e.*, the base of the columns of Morgagni to the "white line" of Hilton, which has already been referred to in this paper). The Author finds that Abel's pecten band corresponds to the anal intermuscular septum, which is the lower circular fibrous portion of the longitudinal muscle of the bowel and which is inserted beneath the skin of the anal canal forming a groove in the normal subject, already referred to as the anal intermuscular septum. The sheath of the longitudinal muscle takes part in the fibrotic process which produces the marked narrowing of the canal. The anal intermuscular septum has become hypertrophied and dense and the Author at present regards this circular fibrous structure as the pecten band referred to in Abel's work. Where anal stenosis has occurred due to a chronic irritant, this circular band normally present, and which can be identified in the normal, as a shallow groove formed by its attachment beneath the skin lining the anal canal in the region between the top of the subcutaneous portion of the external sphincter and the lower border of the sphincter ani internus, has become much accentuated. This the Author regards as the structure referred to by Abel as the pecten band. Although the operation of pectenotomy, *i.e.*, division of this band, will afford some relief; one has to deal with a total fixation of the anal musculature up to and including the anorectal ring. In the Author's opinion pectenotomy although beneficial is therefore regarded as inadequate in dealing with anal stenosis.

Spasm of the musculature of the anal canal and stenosis may result from any irritant or insult in this area. Fissure in ano, while the most frequent cause, is only one of these, and the clinician must deal with those cases presenting spasm or actual stenosis in which no fissure can be demonstrated, and in which other causes are operative. Any factor which produces passive venous congestion in the ring of superior haemorrhoidal veins, which lies quite superficially in the submucosa just above the anorectal ring, (which plexus is concerned in the formation of internal haemorrhoids), will act as an irritant to the anal canal and anal musculature, and result in spasm of the sphincter muscles.

The peculiar arrangement in the lower rectum of a loose redundant mucosa overlying a plexus of superficial veins renders the lower rectum a selective site for the formation of varices. Moreover the portal veins (and the large tributaries) which drain the superior haemorrhoidal area are without valves, and very feeble support is afforded the superior haemorrhoidal plexus by the loose redundant mucosa. With the exception of a slight anastomosis on the surface of the rectum, the portal system practically is a closed circuit, where gravity and physiological stasis especially after meals are constantly at work favouring stasis. It may thus be seen that a dilated state in these veins is easily arrived at, and that the formation of internal haemorrhoids (varices) or anal spasm and anal stenosis may singularly or together be manifestations of a state of passive congestion in the haemorrhoidal veins.

Passive congestion in the haemorrhoidal area may result from numerous systemic causes with the secondary development of anal spasm or stenosis, consequent upon systemic disturbances, *e.g.*, portal obstruction in cirrhosis of the liver, abdominal or pelvic tumors, pregnancy, uterine displacements, pelvic inflammatory disease and prostatism (5). Once spasm has become

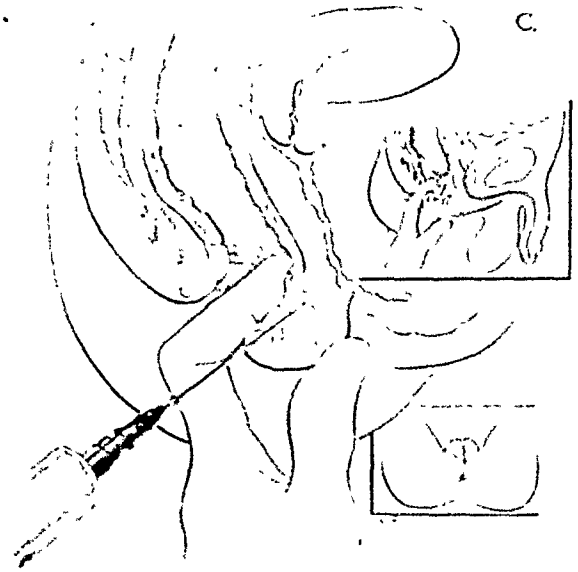

Fig. C. Technique of anterior anesthesia. The large figure shows induction technique in the female. The finger is only inserted for a short distance, up to approximately the first skin crease on its volar aspect. The pulp of the finger is hooked around (5) the anorectal ring. This can be seen lying in a much lower plane than this ring posteriorly. Posterior anaesthesia has already been induced, and the posterior musculature is shown relaxed with the anorectal ring flattened out. (1). The subcutaneous portion of the sphincter ani externus. (2). The superficial portion of the sphincter ani externus. (3). The deep portion of the sphincter ani externus. The sphincter ani internus can be seen lying under the pulp of the finger as a flat muscle.

Fig. C1. Inset—Shows the relation of the anal and anorectal musculature to the bulb of the urethra and other genital organs in the male. Note the distance from the bulb of the urethra, prostate and seminal vesicles. The needle is guided with the finger in the anal canal. In the female the needle is far removed from important structures. In the male the bulb of the urethra is at a safe distance from the area of anaesthesia. The section does not show the pubo-rectalis. Anteriorly this muscle has left the anal musculature and cannot be shown in this plane.

Fig. C2. Dotted area shows the field of anaesthesia induced by the anterior technique.

established the passage of a large bulky stool, (or digital examination roughly or hastily performed), may result in a tear in the lower end of the anal canal, usually in its posterior vulnerable area; then the lesion known as fissure is initiated. The patient who has become aware that liquifaction or softening of the stool is necessary in order to effect its easy passage, usually is fairly comfortable, but even now, for the first time, develops pain and will come seeking urgent relief. The careful, prudent patient may defer the formation of this fissure for months or years by the habitual use of salines or liquid paraffin; thus he may avoid trauma to the narrowed anal canal. In the end, however, the patient is no better off, because, ultimately, stenosis of varying degree will occur. Only too often will one encounter patients who present themselves with an oily-fecal leakage (usually observed when liquid paraffin habitually is taken) and in whom digital examination is not tolerated.

The crypts or pockets of Morgagni which lie just above the pectinate line are of little consequence in the normal subject, in fact are hardly visible during examination of the lower rectum. The passage of liquid or mushy stools is very irritating to the anal canal and one invariably finds reddening and congestion of the anal papillae, (which guard and crown the anal crypts) due to edema, and then easily can visualize the crypts. Retrograde pressure will elicit a mucoid discharge from the pockets and, in some patients, a frank muco-purulent or purulent exudate.

It must be remembered that the crypts of Morgagni mark the junction of the *proctodeum* with the hind gut, and the point of breaking down of the proctodeal membrane. In other words, nature has presented man with another one of its subtle pitfalls at the end of his embryological evolution. In some people, the crypts of Morgagni are very shallow and made out with great difficulty, in fact they may be regarded as almost absent. In such circumstances, one finds only a clean transition from squamous epithelium to columnar epithelium marking the area of anal crypts. In other patients, one finds well developed and deep anal crypts, and these are the cases that develop cryptitis when and if conditions become favorable. In certain instances, Hermann and Desfosses (6), Harris (7), and Lockhart-Mummery (8), have observed racemose, multiglandular structures running out from the bottom of the crypts of Morgagni into the peri-anal tissues. Infection of the crypts of Morgagni (7 and 8) with secondary infection of these glandular structures, these observers regard as the process in peri-anal suppurative lesions. These large multiglandular structures lined with secreting epithelium very frequently have been found in cases of peri-anal suppuration and fistula in ano. Like the crypts of Morgagni, these glandular structures are absent or very rudimentary in many people. In other words, embryologically certain people are by nature made susceptible and vulnerable to the establishment of a cryptitis and to perianal suppuration.

This description of the crypts of Morgagni becomes necessary, because where liquifaction of the stool is habitually indulged in, lodgement of bacterial laden residue in the anal pockets occurs soon or late. The patient now experiences spasm with or without fissure, accompanied by an active cryptitis. The whole picture becomes a vicious circle because the patient must continue the use of liquifying purgatives. Fortunately the infection does not too frequently travel beyond the stage of cryptitis; it is surprising that one does not oftener find peri-anal suppuration. The embryological observations of the authors mentioned above (6, 7 and 8), probably provide the answer to this. The necessity for the use of liquifying purgatives, where spasm has become established, immediately suggests itself to the average patient. This, at least temporarily, provides comfort and keeps the bowels open. There is another group of patients, who, for general health reasons, will begin to indulge in a morning dose of salts, or perhaps take salines at more frequent intervals. Then food residues are hurried through the intestinal tract and the patient begins to have one or more liquid, precipitous stools daily. Passive congestion then is produced in the superior haemorrhoidal veins, spasm follows, (the bulky stretching effect of the motion is lost), and a cryptitis, when the crypts are well developed, becomes established. Liquid paraffin in large doses habitually taken will accomplish a similar result. Thus, one cannot help but regard the ingestion of harsh purgatives, salines or large doses of liquid paraffin as having a deleterious effect upon the ano-rectum (3). The combination of ingestion of alcohol, with a harsh morning saline, habitually taken, has been observed to be a frequent precursor of the clinical picture above described.

Clinical Examination: Patients of this character easily are recognized upon examination. Spasm or

fibrosis of the anal canal is easily determined by digital examination. Where spasm or fibrosis is well established, the patient will not tolerate passage of the index finger. In such instances, passage of the small finger well lubricated and gently passed usually is successful. The presence or absence of fissure should be determined. Marked hypertrophy of the anal papillae often may be discovered. In some patients these are sufficiently prominent as to form actual polypi. One or more may be present. They must be regarded as the result of long standing irritation. The anal canal has a congested unhealthy appearance. Perianal pruritis often is present, particularly when frequent liquid stools have been experienced. In the average patient, it is impossible to pass a rectoscope or to perform sigmoidoscopy. Probably such examination will have to be deferred until anal spasm or stenosis have been overcome. However, in many patients, a rectoscope of small calibre (as that of Kelly) may be introduced. Bensaude's proctoscope is suitable for such cases. The Author has constructed a small tubular proctoscope, which is approximately slightly more than half of the diameter of the Gabriel proctoscope across its lumen. Through it one may see the lower rectum. Often, one will be surprised in such instances to find the ampulla filled with redundant mucous membrane and large varices covered by an unhealthy granular mucosa. These have not been extruded because of the sphincter spasm. They are evidences of passive congestion, straining and long continued purgation. When the spasm has been relieved and the patient's normal bowel habit has become established after a short time one may notice improvement in this mucous membrane redundancy and the varices will appreciably diminish. In many patients it becomes necessary to defer treatment of the mucous membrane redundancy and hemorrhoids.

TREATMENT BY CONSERVATIVE MEASURES BASED UPON THE PRINCIPLE OF REST

The treatment to be outlined essentially is ambulant and non-operative. It is based upon the surgical axioms of Hilton in his Lectures on "Rest and Pain" delivered to the Royal College of Surgeons in London, 1860, 1861 and 1862, and upon his teachings in Guy's Hospital, London, where he emphatically taught by lectures, and demonstrated clinically in the wards, the therapeutic value of mechanical and physiological rest in surgery (1).

Hilton based his reasoning upon anatomical facts and applied these facts to the needs of daily surgical practice. It is upon a thorough and scientific of the anatomy of the anal canal and ano-rectum, with the application of this knowledge, which forms the main premise upon which treatment of anal fissure, anal spasm and anal stenosis is carried out in this communication. Hilton emphasized the need for rest in lesions of the rectum. He states in his lectures that "rest is a most important therapeutic agent in the cure of accidents and surgical diseases". He states again "I depicted the instinctive promptings of nature to secure rest on the occurrence of accident or disease. Lastly, I attempted to shadow forth the different appliances for the attainment of rest with which that surgeon only will become familiar who has an accurate knowledge of the anatomy and physiology of the different parts which he may be called upon to treat." Hilton described dorsal ulcer of the anus. He described referred symptoms to the bladder, to the knee and thigh reflexes and to the genital organs, resulting from fissure. He emphasizes the need for physiological and mechanical rest to the sphincter. He recommends the recumbent position, soft diet and discussed the value of silver nitrate or bichloride of mercury to the fissure which forms an adherent albuminous defence to the raw surface and thus provides rest by covering the denuded surface and [illegible]. He regards albumen-coagulating agents for this reason as quite valuable. Where the ulcer had become chronic Hilton divided the sphincter fibres with the bistoury knife in order to secure mechanical and physiological rest.

The substance of this thesis is the presentation of a method of securing mechanical and physiological rest by the employment of oil-soluble anaesthetics in these lesions based upon a knowledge of the anatomy of the parts.

Oil-Soluble Anaesthetics. The use of oil anaesthetics in rectal surgery was first introduced by Yeomans, Gorsch and Mathesheimer in 1927 (9). These workers used a solution consisting of equal parts of para-amino-benzoyl-benzoate and phenomethylol in ninety parts of rectified sweet almond oil. They found this injection far superior to that of alcohol in producing anaesthesia for the relief of pruritis ani. Anaesthesia producing agents when dissolved in an oily base and injected into the tissues, produce a prolonged period of anaesthesia affecting the parts immediately injected and the nerves coursing through these parts with the areas supplied by them. The injection of anaesthetic substances dissolved in water will produce anaesthesia of only short duration; on the other hand the injection of oil-soluble anaesthetics (sweet almond or olive oil as the base) will because of the very slow liberation of the anaesthetic agent from its oily base and its slow rate of absorption, produce local anaesthesia and relaxation, *i.e.*, sensory and motor anaesthesia for varying periods. Such period may range from days to several weeks. If the induction is properly carried out, a profound local anaesthesia both sensory and motor may be obtained. During this time there is a complete interception of painful or uncomfortable stimuli and relaxation of the musculature, providing actual stenosis or fibrosis has not already become established.

In 1929, in London at St. Mark's Hospital, Gabriel (10) introduced a preparation known as "ABA," a 3% solution of anaesthesin, benzyl alcohol, 5%, and ether 10% in almond oil. He also introduced an alternate solution of "percaine in oil"; this consists of percaine, ½ of 1%, benzyl alcohol, 10% and phenol 1%, in olive oil. Gabriel found that these solutions produced profound anaesthesia when injected and were of decided value in chronic pruritis ani and in acute fissures. In chronic fissures, he considers that operative interference is necessary. This he accomplishes by dissecting out the anal ulcer together with a large wedge-shaped area of skin dorsally between the anal canal and coccyx; such may measure approximately 2¼ inches in length. This radical operation Gabriel performs so as to secure adequate drainage and to insure healing within the anal canal before external healing takes place. The patient's stay in hospital is approximately three weeks.

Morgan (11), in a recent paper published in the British Medical Journal, introduces a new anaesthetic-oil which he calls "Proctocaine." It consists of procaine base, 1½%, butyl-para-amino-benzoate, 6%, benzyl alcohol, 5% in almond oil. He regards this preparation as comparatively non-toxic. He finds that it produces profound anaesthesia lasting from seven to twenty-eight days or longer; that there is no immediate after pain following injection, and that the preparation is very well tolerated by the tissues. Morgan finds that this preparation produces excellent anaesthesia, and that it is very valuable or curative in chronic pruritis ani and acute fissure.

In acute fissure, Gabriel injects his anaesthetic oil into the external sphincter and to each side of it, and uses from five to ten c.c. of "ABA." The whole injection is given dorsally, just behind the centre point of the anal circumference posteriorly, and to each side of this into the sphincter muscle. Morgan points out the need for an adequate induction in treating anal fissure and pruritis ani by the injection of anaesthetic-oils. He observes that since the inferior haemorrhoidal nerve and the perineal branch of the fourth sacral lie deep in the postero-lateral aspects of the ischio-rectal fossa that it is necessary to anaesthetize this area. He further emphasizes the need for introducing anaesthesia up to the anorectal ring; this procedure is based upon the recognition of this anatomical structure. In anal fissure, Morgan's whole injection is carried out dorsally and dorso-laterally. He injects the posterior anal region up to the anorectal ring and includes the dorso-lateral aspects of the ischio-rectal fossae in his induction technique. He records satisfactory results and cures in acute anal fissure, and anal spasm; he has been successful with his anaesthetic oil in carrying out surgical procedures in the anal canal and lower rectum. He has also found that a preoperative injection of proctocaine to be effective in lessening post-operative distress in rectal operations, with his induction technique. He employs proctocaine throughout.

The Author has been employing the principles laid down by Morgan, but has found it necessary to go several steps farther in effecting a radical cure of anal fissure, anal spasm and anal stenosis by the method of

injecting anaesthetic solutions in oil. By the technique described below, the chronic fissure is brought within the realm of ambulant, conservative treatment as is also anal stenosis; in the past such lesions have been amenable only to radical, surgical measures.

AUTHOR'S TECHNIQUE OF TREATMENT, OF ANAL FISSURE, ANAL SPASM AND ANAL STENOSIS

Our observations are based upon an unselected series of approximately fifty patients, who, during a period of two years, presented themselves with the lesions of acute or chronic fissure, anal spasm or anal stenosis. The duration of disability ranged from several weeks, to months and years. Several of the patients had symptoms of many years' duration: it was not uncommon to obtain a history in which a middle-aged-patient would date discomfort back to adolescence.

The results secured by the technique to be mentioned uniformly have been good in all three lesions, regardless of the time duration of the affection. The cases of long standing who had chronic, well established changes, required more thorough and adequate treatment and after care, but in the end exhibited satisfactory and happy results. For this reason the Author believes it unnecessary to tabulate the various cases who presented the lesions in various stages of their evolution, and who were all treated by the same technique. The cases reviewed and treated are divisible into the following groups:

(a) *Acute anal fissure*, usually dorsal: simple muscle spasm is always present; (b) *Chronic anal fissure, usually dorsal:* the whole anal canal is fixed and there is an actual stenosis of the lumen. (Spasm replaced by fibrous changes of the anal and anorectal musculature, not relaxed under spinal anaesthesia); (c) *Anal spasm, without fissure:* these cases all show varying degrees of inflammation of the anal crypts of Morgagni and accompanying the cryptitis, the papillae crowning the crypts are edematous, inflamed and often hypertrophied, and (d) *Anal stenosis, without fissure:* these cases show a marked cryptitis and papillitis; the papillae may be polypoid; large redundant mucosae and varices (internal haemorrhoids) are sometimes present above the stenosed anal canal and not extruded because of the very narrow and fixed anus; pathology as shown (c) and (d) may at any time develop fissure in ano.

After the anal diameter has been returned to normal or near normal, the patient may for the first time extrude the mucosal redundancy or the haemorrhoidal tissue. *The hemorrhoids may subside after a time* or may need to be dealt with by submucous injections or operation (12). The etiology and evolution of these lesions already has been discussed.

The anaesthetic oil employed in the majority of the patients has been the English "ABA." About a year ago the anaesthetic components of the original preparation were somewhat modified and the preparation became known as "ABA No. 2." This was supplied by Allen and Hanburys, London, when ordinary ABA was asked for and replaced the original ABA. This newer preparation appeared to have a more positive action and to give a somewhat longer period of anaesthesia. Gabriel's percaine in oil was early discontinued. Several sloughs were encountered unless the solution was placed deeply; this is not always possible. Such reaction was regarded as due to its 1% phenol content, and never once was a slough encountered with the old or newer ABA. For the past few months, Morgan's "Proctocaine" has been given a trial to the complete exclusion of ABA. This also is supplied by Allen and Hanburys-London, and appears to compare very favorable with ABA No. 2. It has at least two advantages over ABA No. 2 as evident to the writer in the short time that it has been employed. It produces a more immediate anaesthetic effect (ABA *may* take several minutes longer before anaesthesia becomes established) which appears to be more thorough and marked than even the newer ABA. Minor surgical operations may be carried out in the anal canal under this anaesthetic oil. This is a great advantage. The anaesthesia is more prolonged than either the old or new ABA. It is not unusual to find that the anaesthetic effect persists after two, three and four weeks. The preparation appears to have a very low degree of toxicity. Doses of five to fifteen CCs are well tolerated and no untoward effects have thus far been observed. The writer feels from his short experience with this preparation that "Proctocaine" as an anaesthetic oil is superior to ABA and has distinct advantages over these older preparations known as ABA, and ABA No. 2.

(a) Acute anal fissure (dorsal). In this lesion, posterior and postero-lateral anaesthesia is induced embracing the whole of the anal and anorectal musculature posteriorly, together with the posterior half of the ischio-rectal fossa bordering upon the anal canal laterally. This will include the postero-lateral aspect of the ischio-rectal fossa across which run the inferior haemorrhoidal and perineal nerves.

Technique. The patient lies on the right side in the right Sims' position with the knees drawn up at the edge of a firm table. The operator sits on a low stool opposite the flexure of the patient's knees at the lower end of the table. The area is shaved and cleansed and prepared with spirit and tincture of "metaphen." A skin wheal is raised with 2% novocaine at a centre point of the posterior peri-anal area just at the outer border of the subcutaneous portion of the external sphincter. A one or one and a half inch hypodermic needle of the smallest available bore is employed in raising this wheal. A few minims of the novocaine are now injected into the deeper skin layers dorsally, into the deeper subcutaneous tissues and into the outer subcutaneous sphincter fibres. In all about one to one and one-half cubic centimeters of 2% novocaine may be employed. This preliminary detail makes the subsequent puncture and penetration by the larger needle quite painless. Quite often the patient will feel nothing further after this. A two and one-half or three inch length, size 20-21 gauge needle with a 10 c.c. Luer, lock syringe is ready. A short size, 18 gauge needle is available for sucking up the oily "proctocaine" into the syringe. The proctocaine is placed in the hot steriliser and warmed for several minutes or it may be placed in hot water for a few minutes. The syringe is now loaded and the long two and one-half to three inch needle locked into the syringe. As shown in Fig. 1 the lubricated left index finger is placed in the anal canal with the volar aspect (pulp) of the finger pointing dorsally. The end of the finger is hooked around the ridge of the anorectal ring which lies approximately two inches from the anal opening. The finger is inserted to the second skin crease. The needle must be at least two and one-half to three inches in length because one must inject up to and including the anorectal ring, and at least half to one inch of working needle must be available. It is unwise to plunge the needle up to its hilt, unless an extra guard is present as in intra-spinal needles. For this reason a longer needle provides safety. The needle is advanced through the skin wheal and the oily solution is slowly injected. It is kept about a quarter to half an inch away from the anal canal and care must be taken that the needle does not perforate the anal canal or lower rectum. The fibres of the subcutaneous portion of the external sphincter are first injected. As the needle advances the operator perforates a fibrous resistant layer. This is the anal intermuscular septum, i.e., the lower fibrous portion of the longitudinal muscle of the bowel. The lower border of the internal sphincter is now injected. The needle advances further and enters the superficial portion of the external sphincter. The oily solution is injected right into these muscles. The needle again advances into the deep portion of the external sphincter. The injection is slowly and evenly continued. The puborectalis portion of the levator ani is now entered where it joins with the deep portion of the external sphincter and the longitudinal muscle fibres of the bowel to form the anorectal ring. The anorectal ring which up until this time has maintained its identity, in that the finger has remained hooked around its ridge in the anal canal as a definite entity, now dissolves so to speak away under one's finger and becomes flattened out. This is what determines whether one has reached and injected the anorectal ring with its levator fibres. Unless this succeeds adequate relaxation will not be obtained. This, doubtless, is a frequent cause for failure to cure an acute fissure by the injection of anaesthetic oils. One must inject deeply until one is certain that one has anaesthetized this anorectal

ring. The criterion of this consists of its disappearance and flattening out under the pulp of the left index finger in the anal canal. The needle is now not completely withdrawn but only up to the original skin puncture. Approximately five CCs of the oil anaesthetic have thus far been utilized. The finger is now turned laterally facing the left ischio-rectal fossa. The subcutaneous portion of the whole posterior and postero-lateral half of the ischio-rectal fossa is injected with the anaesthetic oil. As one approaches the anal canal in its lateral aspect some of the musculature which is not yet relaxed will be included in the injection. The right ischio-rectal area, *i.e.*, the right lateral portion of the anal canal and its bordering fossa are likewise injected in turn, by turning the pulp of the index finger to the right and guiding the needle to the right ischio-rectal region. After the ischio-rectal fossae (and their coursing inferior haemorrhoidal and perineal nerves) have been anaesthetized the needle is pointed in the same plane as the anal canal and a few CCs of the solution injected into the lateral peri-anal masculature as deep as the anorectal ring. (Approximately a depth of two inches) 2.5 to 5 c.c. are employed in each lateral injection, the total injection totalling 10-15 c.c. Following a satisfactory induction, the spastic anal canal has become relaxed and digital examination can be painlessly and deliberately performed. The tissues surrounding the anal canal in its posterior and both lateral boundaries now is massaged for several moments by gentle external pressure. At no time must a subcutaneous bulge be visible during the injection, in other words one must avoid pooling in the subcutaneous tissues.

The next step is very important. One waits about five minutes keeping up firm massage in the *interum*. Both index fingers are now well lubricated and inserted through the anal canal to the height of the anorectal ring, the backs in apposition and the pulp of both fingers facing laterally. The whole of the anal canal, including the anorectal area, with its surrounding musculature, is now gently dilated until one can easily insert a large proctoscope or three fingers. This stretching is at first resisted by the patient, who perceives no pain, but is conscious of the stretching force. If this is previously explained the patient will not attempt to resist this gentle dilatation which although uncomfortable is not painful. Under combined anterior anaesthesia to be dealt with, this dilatation is much facilitated and more easily carried out.

The fissure is painted with 5% mercurochrome and the patient seen every day. A small pledget of absorbent cotton is placed over the anal orifice and if gently teased out will stay in position. A drop of ichthyol or balsam of Peru is placed on the fissure every day with a wooden applicator and the well lubricated index, middle finger and thumb or graduated bougies (St. Mark's) are daily passed to maintain the dilatation and to encourage healing.

After-care A hot hip bath the night of the same day as the injection and a hot tub every second day is recommended and helps in the healing of the ulcer. The hot hip bath following the injection prevents pooling of the injected oil anaesthetic and gives the patient much comfort. There is usually no pain following the induction, especially since the advent of proctocaine. All purgatives are discontinued. The patient is placed upon a normal diet and encouraged to have natural bowel movements without assistance. The passage of a bulky, formed stool is desirable and the habit of passing liquid or mushy stools under the stimulus of purgation, must be early broken. It may take some time before the patient's stools again become formed, because, preoperatively, the bowel may have been much irritated. "Normacol" crystals or "Metamucil" (Searle) are very helpful in those cases whose stools continue loose or mushy. A dessert-spoonful at bedtime in water is a satisfactory dose. The patient is watched until the fissure has completely healed and no further spasm is present. This may take several weeks or a month, during which time the anaesthesia usually persists.

(b) Chronic anal fissure. Posterior and postero-lateral anaesthesia is induced as described under acute fissure. After induction, digital examination is quite painless and there is some discernible relaxation of the anal and anorectal musculature. The anal stenosis may be the result of spasm as well as fibrosis, and therefore where the chronicity is not too well established, a degree of relaxation will be elicited by the dorsal anaesthesia. The next step consists of a careful examination of the fissure. If possible this should not be disturbed. The anterior anaesthesia *(vide infra)* with its resultant relaxation, together with the daily after-care will more often than not result in healing of the lesion. The posterior anaesthesia induced by the "proctocaine," is usually ample for any intra-anal minor surgical procedures. Any dissection of perianal skin, outside the anal canal, may require a few drops of 2% novocaine. Obvious interference with dorsal drainage at the base of the fissure, such as by a sentinel skin tag (sometimes present in very chronic fissures, the result of anal contraction) should be attended to by simple ablation of the tag. In certain cases the lesion has become cartilaginous. Simple trimming of the edges of the fissure with eye scissors should be carried out. If the base of the ulcer has become undermined to form a superficial subcutaneous tract, this will require to be laid open. Any large hypertrophied papilla which prolapses or which forms the apex of the fissure should be crushed and snipped away. Seldom should it be necessary to dissect away the lesion. No perianal skin is cut away, with the exception of a "sentinel," dorsal tag, if one be present. Whenever possible it is advisable to carry out posterior and anterior anaesthesia, without practising any surgical procedure. Should healing of the anal lesion fail to occur after a month and symptoms recur, then one may lesion fail ot occur after a month and symptoms recur, then one may dissect out the fissure under posterior anaesthesia, followed by the anterior block at once or within forty-eight hours. Patients will be seen whose anal circumferences have been restored to normal but in whom the dorsal ulcer has been replaced by a firm, painless cicatrix. This is the result of the chronicity of the lesion and nothing further need be attempted. Bowel movements are comfortable and the motions are formed and bulky. Following the induction of anaesthesia, careful after care to the fissure, such as daily applications and the passage of bougies, is essential.

The next important step consists in the induction of anterior anaesthesia. This may be done immediately following the posterior induction or deferred for two or three days. Where any intra-anal surgical procedure has been carried out, it is better to defer the anterior induction for several days. Although some measure of relaxation may have been elicited by the posterior induction, this is immediately lost should any intra-anal surgical procedure be performed. The remaining portion of the anal and anorectal musculature anteriorly which is still unanaesthetized, has responded by spasm, consequent upon the operative procedure. This is taken care of by the anterior induction, when relaxation results at once, or is easily established by gentle dilatation, which is well tolerated.

After-care: The patient whose duties are not too onerous may continue at work after anaesthesia has been induced. When minor surgery has been practiced, or when the injections tire the patient, a day or two of rest at home is advisable. Long motor journeys or vigorous exercise should be forbidden for some weeks. Robust patients do not mind the induction of the anaesthesia in the least. Nervous, frail people may be somewhat upset, and should rest around the house for a day or two taking a daily hot hip bath in the *interim*.

Anterior anaesthesia is carried out as follows: The patient lies on the left side at the edge of the table in the left Sims' position with the knees drawn up. The operator sits at the end of the table opposite the flexure of the patient's knees. The skin is prepared as for posterior anaesthesia. A novocaine wheal is raised at the centre point anteriorly just in front of the skin overlying the subcutaneous portion of the external sphincter. The subcutaneous tissues deep to this are infiltrated with about half to 1 c.c. of the 2% novocaine solution. This skin wheal in the male corresponds to the area between the outer border of the subcutaneous portion of the external sphincter and the central point of the perineum, and in the female to the area between the outer border of the subcutaneous sphincter muscle and the beginning of the perineal body. The lubricated left index finger is gently inserted into the anal canal with the pulp of the finger facing the prostate in the male and the vagina in the female. It must be remembered that the anorectal ring anteriorly lies at a distance of approximately one inch from the anal orifice, corresponding roughly to the height of the first skin crease on the volar aspect of the index finger. This represents the height of the area of anesthesia. A one and a half to two inch 21 gauge needle is employed for this anterior injection, in contrast to the two and one-half to three inch length for the posterior injection. In the male the base of the prostate is felt just above the anorectal ring, and in the female the back of the cervix can usually be palpated. The bulb of the urethra in the male is a fair distance anteriorly and superior to the anorectal ring, and there is very little danger of reaching this structure if one recognizes the height of the anorectal ring and has an approximate idea of the relation of the bulb of the urethra to the central point of the perineum. To each side of the anorectal ring the puborectalis portion of the levatores ani muscles can be felt leaving the anal canal, running forward. It will be remembered that anteriorly the anorectal ring is formed by the fusing of the deep portion of the external sphincter and the longitudinal muscle of the bowel, reinforced medially by the inner circular muscle fibres of the bowel (upper border of the internal sphincter, which is really a flat and not an annular muscle band). The ring anteriorly, because of the absence of the puborectalis in its formation, is not so prominent as posteriorly.

A 10 c.c. Luer lock syringe is loaded with the Proctocaine solution. The needle passes through the skin wheal and enters first the fibres of the subcutaneous portion of the external sphincter. It passes quite superficially through the fascia of the longtitudinal muscle which is inserted beneath the skin of the anal canal to form the anal inter-

muscular septum. Next the lower border of the sphincter ani internus is entered. All this time the injection is being continued with a slow even pressure. The lower border of the superficial portion of the external sphincter lies only a millimetre or two above this and is soon entered. This is next injected. Next one enters the deep portion of the external sphincter muscle as it enters into the formation of the ano-rectal ring. One has now only traversed a distance of approximately one inch. In the male the anorectal ring is just below the base of the prostate and in the female this lies below the level of the cervix uteri. The needle is now slightly withdrawn and pointed in an anterolateral direction to each side of the middle line and one now injects the fibres of the puborectalis portion of the levatores ani muscles as they leave the ano-rectum. In all one injects only about 5 c.c. of the anaesthetic all arterially, because one has less area to traverse and therefore less to anaesthetize. In pregnant women who suffer from rectocele one will not attempt to inject the puborectalis muscles, which are in such cases retracted or absent. In such cases one stays within the thinned rectovaginal septum while injecting into the anal and anorectal musculature.

After anterior anaesthesia has been induced one may recognize a measure of real relaxation even in those cases that have a well developed fibre of the anal and anorectal musculature. The anaesthetized levatores ani muscles (puborectalis) permit the anal canal to fall away as it opens, and the anaesthetized short anal canal arteri shows at once a full measure of relaxation. Full dilatation as described under posterior anaesthesia is now completed and where too little relaxation has been experienced, a slightly firmer stretching force is exerted for several minutes. Anaesthetization by this technique of the short anal canal arteriole with relaxation of the levator group affords a full measure of relaxation, particularly so if dilatation has been exercised. When anterior anaesthesia has been induced a moderate degree of dilatation should be practiced. This is very beneficial. Relaxation may be so complete that one may have misgivings about the patient's continence during the duration of the anaesthesia (2 to 4 weeks). Even after full dilatation, one has very little difficulty on this score. Attention is directed to the formation of bulky faecal stools as already described and all laxatives are forbidden.

Section of the external sphincter (really only its subcutaneous part) has been described by some authors as adequate in dealing with spasm and chronic fissure. Its application has been criticized. One is dealing with a lesion of the whole anal and anorectal musculature (or an anal fissure which may be part of the levatores sphincter complex) to be truly relieved. By the Author's technique one gently stretches (quite different from forcible dilatation) under adequate anaesthesia a completely anaesthetized and resting anal and anorectal musculature. One very rarely encounters bleeding and in the Author's cases it has never been necessary to catheterize any of the cases. There is a very different between faecal distension of the anal canal as it sometimes part vomit under general anaesthesia or even spinal anaesthesia and the gentle stretching of a completely relaxed and anaesthetized musculature. During this gentle dilatation one can actually feel the tissues give way. Slight tears of the anal skin which have become adherent and contracted are of no consequence and heal within a few days. If the rectal infection follows the posterior anaesthesia by several days dilatation can still be comfortably carried out at the end of this time.

Although it is wise to carry out a preliminary posterior block before attempting the anterior anaesthesia, this is rarely impossible. There may be an infected dermal area in very chronic fissure or submucous pyogenic external. In such cases anterior anaesthesia without posterior injection directed at the short submucosal canal anteriorly has been found to give splendid relaxation and permit complete visualization and local treatment to the fissure. In anterior fissure although the nerve supply to the anal canal is not intercepted by anaesthetizing the *ischio-rectal fossae*, and although it will not control the pain of a dorsal ulcer, nevertheless one can produce anal relaxation and thus permit treatment and topical application to the lesion which hitherto has been out of sight because of spasm or fibrosis. In anterior fissure in ano simple anterior anaesthesia is adequate, with the usual after care of the lesion.

(c) Anal spasm. In cases of simple spasm, posterior anaesthesia alone or supplemented by anterior anaesthesia is sufficient to secure relaxation. Gentle dilatation is practiced. Any large hypertrophied papilla which prolapses down is crushed at its base and nipped off. The finger or bougies are passed daily. It may be wise to interdict alcohol and condiments for a time. No attempt is made to cut down or lay open any of the infected crypts (cryptotomy). This is a procedure of very questionable benefit *especially in the light of the work* already quoted (6, 7, and 8). With the relief of the spasm followed by sufficient after care, there is eventually a marked improvement of the cryptitis. Edema of the papillae subsides, the crypts and anal canal lose their contested appearance and discharge from the pockets if present ceases or is lessened. The case is followed for six to eight weeks and seen at least two or three times a week and if possible daily for at least the first fortnight. The openings of the crypts are touched up with 5% aqueous mercurochrome at every visit. Simple massage of the finger or bougie empties the pockets of any discharge by retrograde pressure.

Aftercare. Any soothing ointment is ordered for the anal canal. The passage of bulky formed stools is very beneficial. Nothing further is done. This plan has been quite adequate and infrequently after several months may need to be repeated once. Once the lumen of the anal canal has been returned to normal there appears to be very little tendency to a return of the spasm.

(d) Anal stenosis. This lesion is dealt with by combined posterior and anterior anaesthesia together with adequate dilatation. The cryptitis is dealt with as under (c). A reasonable period of after care is insisted upon together with the regular passage of bougies. It is frequently necessary after a few months to repeat the anaesthesia. Once the lumen has been returned to normal there is little tendency for recurrence.

SUMMARY AND CONCLUSIONS

A study of anal fissure, anal spasm and anal stenosis is presented. The evolution of these lesions is described.

The anatomy of the anal canal and ano-rectum is presented because of its important bearing upon treatment.

Treatment is based upon the principle of Hilton, namely, the securing of adequate mechanical and physiological rest to the affected parts. Based upon the principle of rest, the Author has presented his plan of treatment.

The carrying out of the described technique necessitates careful attention to anatomical structures and landmarks.

The treatment is essentially conservative and ambulant, and in the Author's experience has greatly reduced the number of cases which need to be treated by radical surgical measures.

SECTION VIII—*Editorial*

NOTE: The editorial contributions published in this Journal represent only the opinions of their writers. Such being the case, this Journal or the American Gastro-enterological Association is in no way responsible for editorial expressions.

ENDEMIC DYSENTERY: SIGNIFICANCE AND DIAGNOSIS

ENDEMIC dysentery is a common occurrence in this and probably other countries. In the past summer alone, there were six outbreaks of endemic diarrhea in summer camps of New York State which were traced to dysentery or dysentery-like organisms. Attempts have frequently been made to link up this constantly recurring bacillary dysentery with the increasing incidence of ulcerative colitis. Certainly if there is such a disease as chronic bacillary dysentery it is pathologically and probably clinically indistinguishable from what we now recognize an "non-specific" ulcerative colitis.

But what constitutes a diagnosis of dysentery, particularly in the chronic form? Rarely are we sufficiently fortunate to find a positive stool culture. Phage is unreliable as a diagnostic phenomena; serum agglutination is open to wide variations of interpretation.

In this issue of the *Journal* an article in the nature of a critique has been offered by Dr. A. Penner in which he surveys, in a dispossionate and scientific manner, the natural limitations of the diagnosis of dysentery, thus defining one of the premises to a possible relationship between the two diseases, *e.g.* nonspecific ulcerative colitis and endemic dysentery.

Dr. Penner particularly calls attention to the interpretation of the specific agglutinins in the serum of the patient. Carelessly, many physicians place a diagnosis of dysentery upon agglutinations of 1:40 to 1:80. The unreliability of such a diagnosis is well known to all professional pathologists, but not usually understood by practitioners.

The caution and warning contained in Dr. Penner's article regarding such an interpretation are emphasized and deserve most careful reading.

Burrill B. Crohn, New York City.

A BOLD SUGGESTION

ELMER H. BOBST, President of Hoffman-La-Roche, Inc., writing in "Roche Review," offers a tentative solution for a number of medical economic problems, by making the suggestion that all the recognized and ethical pharmaceutical houses band together and subscribe a very large sum of money each year which would be placed at the disposal of the A.M.A. for the sole purpose of ethically advertising the medical profession via broad radio hook-ups at the most preferred hours, once weekly, using types of programs second to none now in use. Such a program, Mr. Bobst believes, would do a great deal to divert money now spent on patent medicines into regular ethical channels and thus frankly into the coffers of the ethical pharmaceutical firms too. The source of the funds would not, under Mr. Bobst's plan, be revealed to the public. Furthermore he makes the point that such a program might have a deterring effect upon the possible establishment of controlled medicine. He gives evidence of sincerity in promising from Hoffmann-LaRoche $20,000 annually for the next five years, provided other firms of repute contribute equally. Surely this suggestion of Mr. Bobst's is something at least to provoke thought among physicians. It seems unlikely however that our present code of ethics could sanction such a proposal. Nevertheless circumstances alter cases and we are living in an age when new fashions in many of our sociological garments are more than noticeable.

Beaumont S. Cornell, Fort Wayne.

GASTRIC ACIDITY AND ERYTHROCYTE COUNT

To the Editor:

IN an article under the title "The Relation of Gastric Acidity to the Erythrocyte Content of the Blood" in your issue of September, 1936, Apperly and Cary state that it was Apperly and Crabtree who showed in 1931 that the concentration of HCl in the human stomach after a test meal was regulated by the CO_2 content of the plasma of the fasting subject, and furthermore that this was found to be true also when different normal individuals were compared.

I wish to call your attention to the fact that this observation was made and described first by me (*Klin. Woch.*, 3:1951, 1924), and that I subsequently enlarged upon this subject in several publications (A New Approach to Dietetic Therapy; Metabolism of Water and Minerals and Its Disturbances, Boston, 1933; *The Lancet*, 1:1035, 1936, etc.). I showed in addition that in reality it is the concentration of all the acid substances in the blood, rather than that of CO_2 alone, that in accordance with the rules of physicochemistry, influenced the concentration of HCl in the gastric cavity. The acid substance of the blood which is quantitatively most important is CO_2 and since the variations in the concentration of this acid are the most common occurrences, in most (but not all) cases a parallel behavior might be found between its concentration in the blood and the gastric acidity.

Other statements made by Apperly and Cary are that there is a relationship between the gastric acidity and the red cell content of the blood and that anemia can bring about achlorhydria so that in certain conditions where anemia is associated with achlorhydria, the entity which they call "anemic achlorhydria" must be considered in addition to "achlorhydric anemia." These observations also were first published by me in the year 1924. In one publication (*Zeitschr. f. d. ges. exp. Med.*, 41:342, 1924) I described my findings in a statement, according to which the higher the percentual volume of the red blood cells in the whole blood ("hematocrit value") the higher the gastric acidity. The existence of this relationship was explained by the observation that both the hematocrit figure and

the gastric acidity are governed by the concentration of the acid substances in the blood.

Mention should be made, however, of the fact that the red blood cells behave in the blood as acid substances so that not only are these former influenced by the concentration of the latter, but that the red blood cells in their turn influence the concentration of the acid substances in the blood, hence influence the gastric acidity as well. Consequently a hypochlorhydria or achlorhydria may follow if there is a decrease in the red blood cell content of the blood, an occurrence which I described in 1924 as "hematogenous hypochlorhydria or achlorhydria" *(Zeitschr. f. d. ges. exp. Med.,* 43:247, 1924), and to which Apperly's "anemic achlorhydria" corresponds.

Eugene Földes, New York City.

DR. APPERLY'S REPLY

DR. Foldes has raised the question of priority in two matters:

(1) The relationship of the CO_2 content of the plasma of the fasting subject to gastric acidity in a subsequent test-meal. In 1921, Bennett and Dodds (1) showed, as incidental to their main theme, a parallelism between the fasting alveolar CO_2 and a later gastric acidity. In 1922 Kauders and Porges (2) published similar experimental figures. In 1924, Foldes quoted these figures in a paper *(Klin. Woch.,* 1924, 3, 1951) and proceeded to build up a theory of secretion without however, up to that point, mentioning any experimental work of his own on either alveolar or plasma CO_2, or even quoting the source of the above figures in his book ("A New Approach to Dietetic Therapy"). In 1927, Semmens and I (3), knowing that plasma CO_2 generally, but not always, parallels alveolar CO_2, and would be less liable to variation in short periods of time, decided to determine if a similar parallelism existed between plasma CO_2 and gastric acidity. Our results, elaborated by Crabtree and myself (4) in 1931, showed this relationship to be a very close one. *These facts do not bear out Foldes'* claim to priority.

(2) The relation of gastric acidity to red cell content of blood. In his paper *(Zeitschr. f. d. ges. exp. Med.,* 41:342, 1924) Foldes deals only with variations in acidity in people with a *normal* red cell count (this normal figure or its limits are not stated in the article referred to), regarding hematocrit variations as indication of swelling or shrinking of red cells, *i.e.* as due to variations in *"acid valencies"* ("saueren Valenzen") of the blood. This is a matter entirely different from our work. Cary and I (5) were concerned with the relation of gastric acidity to *red cell count* of blood, using our much larger hematocrit variations as indications of *anemia* or *polycythemia.* Nowhere in the paper referred to above does Foldes show any figures or refer to any such relationship as that shown by us. *Again, it seems to us, Foldes fails in his claim to* priority.

SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

"Disturbios do transito duodenal," G. S. De Paula E. Silva, M.D. Published by Graphica Queiroz Bregner, Bello Horizonte, Brazil, 1936. Price, not stated.

DR. De Paula E. Silva has written a very creditable and easily readable monograph on disturbances in and, particularly, slowing of the transit of material through the duodenum. After reviewing the literature, he analyzes the findings in eighty-seven cases which were discovered during the examination of 800 patients with digestive disturbances. To many North American observers, this would seem too high an incidence, but doubtless the more carefully one looks for these things the more often they can be found. The big problem is how much significance to attach to them. Here in the United States, most men pay little attention to them unless they can be demonstrated on repeated examinations. *Certainly it rarely pays to* operate to correct them.

Dr. De Paula E. Silva believed that in a good many cases the changes observed were due to a certain amount of duodenitis and some of the stagnation may have been due to pressure by an abnormal mesenteric root. In general, the outlook is not serious and, as already stated, it is rarely necessary to operate. As the author wisely says, the treatment depends on the necessities of the individual case.

Most of the patients seen were young. There were frequent intervals of freedom from symptoms. Many of the patients had mild colicky pain, usually after meals. As one would expect, this pain was usually in the upper part of the abdomen. Unfortunately, the symptoms were commonly those of many types of organic and functional digestive diseases and there was nothing very characteristic about the syndrome observed.

Such a piece of work would be creditable if it were done by someone in a large center of learning so it is particularly creditable when done by a young man living in a small city far from the mental stimuli and the helps which come from association with able men in a large university.

SECTION XII—"*The Clinic*"

Multiple Primary Melanomas of the Small Intestine

By

FRANK R. MENNE, M.D., F.A.C.P.*

and

J. A. P. BEEMAN, A.B.

PORTLAND, OREGON

MELANIN-producing tumors are confusing structures wherever they are found, but when present in the gastro-intestinal tract, they excite additional interest because of their extreme rarity here and the difficulties that arise in explaining the manner of their formation. Summarizing statements in the literature generally point out that melanotic tumors are most frequently found in the rectum, less often in the intestine, occasionally in the gall bladder, bile ducts, esophagus and mouth. In all of these, there arises the doubt as to whether they are primary or secondary manifestations.

Next to the rectum, the small intestine seems to be the most frequent site for melanomas. Thus far, there has been reported a small number of seemingly authentic instances of such primary tumors, namely by Trevis (1) quoted by Libman, Vander Veer (2), Kellert (3), Cox and Sloane (4), Peritz (5), and Lung (6). In view of their seeming rarity and because of the numbers present, it is deemed advisable to report the following case of multiple melanotic tumors of the small intestine.

CASE REPORT

H. V., an iron worker, aged 35, born in Oregon, of Dutch descent, was employed and in good health until March, 1935. At this time he began to feel fatigued and to lose weight (30 pounds in 4 months). This was followed by pains in the "pit of the stomach," associated with nausea and vomiting. His bowels moved regularly. At the time of the patient's admission to the Veterans' Administration Facility, Portland, Oregon, he weighed about 200 pounds, his pulse was 170, blood pressure S-110, D-70. There was tenderness over the epigastrium, a soft mass could be felt above the umbilicus. *The X-ray examination* disclosed an uneven defect at the base of the duodental cap with persistent raggedness of the pylorus suggesting an infiltrative pathological process. The patient began to have mental symptoms which led to the diagnosis of tumor of the abdomen, type undetermined, and *dementia precox, hebephrenic type.*

During his confinement in the hospital, his temperature varied between subnormal and 102° with synchronous variations in the pulse and respiration. The pulse rate was always above 90 and most of the time above 100.

Examination of the blood disclosed a progressive secondary anemia (RBC 2,760,000) and a relatively high white count (10 to 12,000). The feces contained occult blood. Gastric analysis revealed a combined HCL of 6, but no free hydrochloric acid, lactic acid being present. No noteworthy changes were present in the urine except for a trace of albumin and a relatively high specific gravity (1.025). On August 28 he was given 500 c.c. of blood. On September 4 an *exploratory laparotomy* was performed (Dr. George E. Pfeiffer), at which time multiple melanotic tumors were observed in the small intestine. This finding was confirmed by a biopsy of a mesenteric lymph node. Following the operation, the patient complained of gas pains, vomited bile, became distended, dyspneic, weak, and died on September 6, 1935, about 9 months after the onset of his symptoms.

The autopsy was performed by one of us (F.R.M.) and revealed the following pertinent pathological changes: multiple melanotic tumors of the small intestine; metastatis melanoma of the mesenteric and omental lymph nodes; metastatic melanoma in the spleen, heart and skin; hypostatic broncho-pneumonia, bilateral; fatty liver; acute emaciation. Further pertinent details were noted as follows: 'When the subcutaneous fat is exposed in the usual midline incision, firm, coarsely lobulated, moderately oily fat is seen, measuring about 2.0 cm. in thickness. When the peritoneum is opened, the intestine bulges upward as if under pressure. The great omentum is found adherent to the peritoneum opposite the surgical incision by fibrinous adhesions. The edges of the surgical wound are roughened, covered with some fibrin and small clots of blood, but healing has not yet fixed them together. The small bowel is of increased caliber; it is greater than that of the large bowel. There are also noted moderate constrictions with ballooning and blackish discoloration of the small bowel. There are a few scattered small, bluish-black, cyst-like bodies in the omentum. In the right upper quadrant, just below the gall bladder there is a large, firm, bluish-black mass. Similar masses are found in the second portion of the duodenum. There are no noteworthy changes in the pylorus. It has a circumference of 4.0 cm. The mucosa of the first 8.0 cm. is intact. The latter has a circumference here of 7.0 cm. Immediately below this there appears a circular, friable, black, fungoid mass that is 11.0 cm. in circumference, 6.5 cm. in width, and about 3.0 cm. in thickness. The mucosa over its surface has been denuded and ends sharply and bluntly at its elevated margin which is about 1.5 cm. above the level of the mucosal folds. The second and third portions of the duodenum are dilated, the circumference being 11.0 cm. There are seen here knob-like or shell-like, flat depositions of

*Professor of Pathology, University of Oregon Medical School; Consulting Pathologist of the Veterans' Administration Facility, Portland, Oregon.

Submitted September 28, 1936.

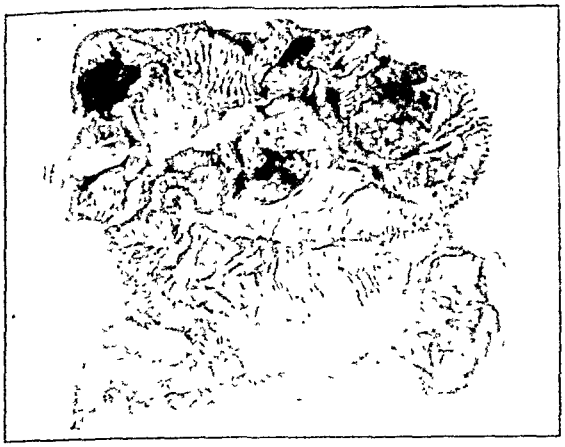

Fig. 1. Autopsy 37-9-35 (H. V.). Photograph of the small intestine showing the character, extent, size and effect of the melanotic tumors of the small intestine. A, upper end, B, lower end, T, larger tumors with superficial black craters.

pigment similar to the pigment seen in the large tumor mass just described. About 17 such small tumors are found in this area, lying between the first large tumor mass and the second which is in the jejunum 10.0 cm. from the ligament of Tritz. This second tumor mass is also circular, similar to the first, somewhat saddle-shaped and measures 7.0 by 7.5 by 4.0 cm. in size. The lumen of the bowel here is 13.5 cm. in circumference so that a small lumen remains in this tumor bed. Now below this second tumor mass there are found six small, knob-like, pigmented nodules that lie in the mucosa, most frequently projecting from the summit of a mucous fold, the mucosa terminating abruptly with serrated edges at the border of a crater that is black. A third large tumor mass is found to lie 14.0 cm. below the second one. This has its longitudinal axis and circling the lumen for a distance of 6.0 cm. It is somewhat boot-shaped and its widest portion is 3.5 cm. The mucosal border is slightly overhanging. There is seen projecting from the center of this defect a fungoid mound, with a broad, sessile base and a granular, slightly irregular surface. It extends upward for a distance of 2.0 cm. and is 2.5 cm. broad. The lumen of the bowel here has a circumference of 11.0 cm. There are three smaller, similarly distributed nodules, the largest 1.5 cm. in diameter immediately below this. Between this third tumor and a fourth large mass, which is 20.0 cm. farther down, there are 9 similar, smaller, black, fungoid masses on the summits of mucous folds and for the most part in line with each other. None of them is over 1.5 cm. in diameter. Now the fourth and largest of the fungoid masses is that which was found lying in the right upper quadrant, apposed to the gall bladder and extending into the transverse mesocolon and is fused rather tightly to the transverse colon near the hepatic flexure with fibrous connective tissue bands that are so dense as to make separation of small portion of bowel, and yet there is no evidence of invasion into mucosa of the colon. This large fungoid mass is covered with serosa and the fused leaves of transverse colon. It projects out pouch-like from the upper surface of the jejunum. The extra intestinal mass measures 12.0 by 6.0 by 12.0 cm. in various dimensions. It communicates with the lumen of the bowel by an irregular, circular, ulcerating opening from which dirty, greenish-gray to yellowish-brown, friable, fungoid masses project. The opening has a maximum diameter of 8.0 cm. (See photograph T4). The circumference of bowel here is about 14.0 cm., while immediately above it is about 15.0 cm. and immediately below it is 8.0 cm. Just below this fourth tumor mass there is seen a rather large, mushroom type of growth that is 5.0 cm. in diameter and is attached to the mucosa of the bowel by a sessile type of pedicle that is only 2.5 cm. in diameter. The overhanging bulk of this tumor mass rests upon normal surrounding mucosa. Immediately near this, there are two other similar, small tumors 1.0 cm. in diameter; and 2.0 cm. in their maximum diameters. From here on down, there are found in addition 25 other small tumors, similar in appearance, location, morphology and color, and varying from 5.0 to 3.5 cm. in their maximum diameters. The last tumor is 45 inches from the ileo-cecal junction. The circumference of the lower end of the ileum is 10.0 cm. All of the above tumors have their maximum distribution and their apparent origin in that portion of bowel that is opposite the mesenteric attachment. While the colon is moderately dilated, there is no evidence of tumor formation here. There are no noteworthy changes in the rectum, bladder or prostate. Including the small ones, there were 61 tumors throughout the small intestine." (See photograph No. 1).

Microscopic examination disclosed a universal similarity of structure in all the tumors. The mucosa at the margins of the tumors seemed frayed, possessing a looseness of structure in part due to edema and also in part to tumor formation with secondary necrosis and infection. The mucosa was found to be undermined, the invasion often extending for a considerable distance in the submucosa. The supportive stroma was scant. The cells were found to be variable in size (anaplasia) with polyhedral peripheries and rather large clear nuclei with single large nucleoli. While considerable hyperchromatism was present, mitoses were not found because of the abundance of intracellular pigment. In most of the tumors, cells were often found in pseudo-acinar arrangement. (See photomicrograph No. 1A). None of the cells showed a tendency to lay down fibrillar processes that could be demonstrated with Van Gieson stains. The abundance of pigment found in these cells as well as the coarseness of granules is best illustrated in photomicrograph No. 2 which also exhibits their character and size. The effect of the latter could be seen in the smaller lymph nodes which had white centers with black circular peripheries, except at the hili, due to retention in the afferent vessels here. (See photomicrograph No. 3). The metastases in the heart were similar.

COMMENT

It is of interest to note that this man in the third decade of life was working and in apparently a good state of health until 9 months prior to his death. His feeling of fatigue, gradual loss of weight, with pain and tenderness in the epigastrium were all undoubt-

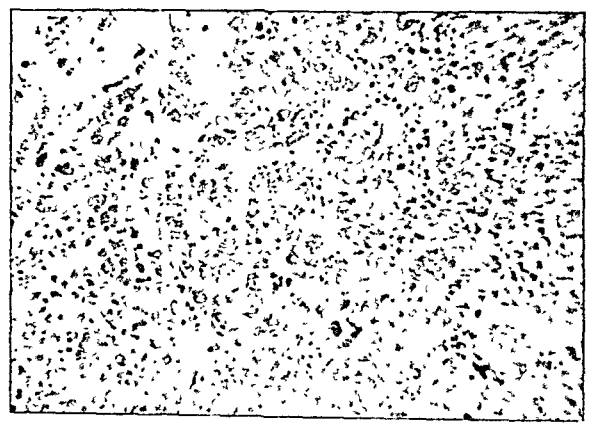

Fig. 2. Autopsy 37-9-36 (H. V.). Photomicrograph No. 1, illustrating the pseudo-glandular character of the growth at A. Note the epithelial character of the cells.

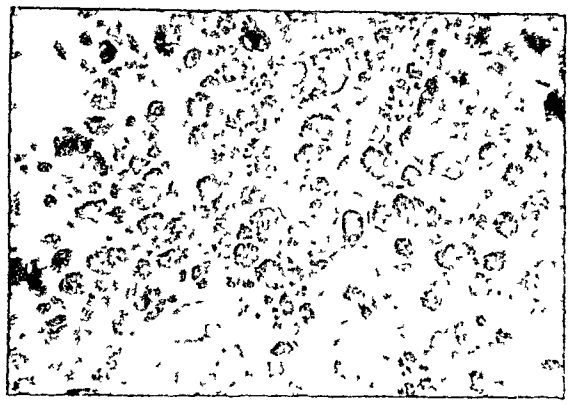

Fig 3 Autopsy 37-9 35 (H. V.). Photomicrograph No. 2, illustrating the pigment-laden cells with epithelial outline of the cytoplasms and a distinctive type of nucleus. Note the abundance of coarse granules of pigment.

edly due to a sluggish digestion, hemorrhage, the absorption of toxic products from the tumors, the excitation of excess peristalsis and the inflammatory reactions which they induced. The oldest tumors were found in the duodenum and upper part of the jejunum. Many of the smaller secondary ones seem to have been implanted at their respective sites. It is also remarkable that there was no evidence of obstruction until late, following the operation, but not due to it, but rather to the bulk of the larger tumors. The absence of free hydrochloric acid in the stomach contents supports the contention that not infrequently there is a lack of this acid in malignant tumors of the intestinal tract, exclusive of stomach involvement. Although permission was not given to examine the brain, there is reason to believe that the symptoms of dementia were secondary to the toxicity from the multiple tumors of the intestine rather than metastases. There is certainly no clinical evidence to lead one to believe that a primary melanoma of the meninges existed. There were found no evidences of a primary tumor other than in the intestines in either the clinical, gross or microscopic studies of this body. The instance here presented is similar to that of Cox and Sloan (3) although the metastases were not as extensive.

While metastatic melanomas of the small intestine are also infrequent (see reports by Maxwell (6), Jones (7), Saphir (8), and others)), the actual instances of the occurrence of such primary tumors here is indeed rare. In addition to the five cases mentioned above, there are references to several others (Lewis (9)). In the case of Cox and Sloan, Wells (H.G.) who performed the autopsy seemed convinced that the melanotic tumor was primary in the jejunum. Likewise Mallory, (F.B.), who passed on the instance reported by Lund, reluctantly regarded it as a primary intestinal tumor, stating that while he had never seen one here, there seemed to be no other primary source. While it is true that the great majority of melanomas (70 to 95%) take their origin from the skin (pigmented nevi) or the choroid of the eye, the ectodermal origin of such cells is by no means a settled question in all instances. Ewing (10) cites the theories of the origin of melanomas as follows: (1) *mesoblastic chromatophores* (Ribbert); (2) *epithelial cells and epithelial chromatophores* (Post and others); (3) *nevus cells in the skin* and *mesoblastic chromatophores* in the *choroid and meninges;* (4) from *endothelial cells of blood* and *lymph vessels* or of *nerve trunks;* (5) from *chromatophores, tactile corpuscles* and *nerve cells forming the end apparatus of the cutaneous sensory nerves* (Masson). Foot (11) subscribed to the views of Masson after a silver impregnation study of nevi. It was his opinion that these cells are derived from the sheath of Schwann. While the latter seems more consistent with our knowledge of pigment distribution and function in animals and man, and while, as Ewing pointed out, it is in harmony with the clinical manifestations, yet the constantly varying character of the cells, which has led us to use the terms "melanoma," "melanosarcoma" and "melanocarcinoma," makes us hold somewhat tenaciously to the type chromatophore, independent of sensory end-organs, in explaining the occurrence of such primary *melanin-bearing tumors as may be found in various* parts of the alimentary tract, other than in the pharynx and the lower end of the rectum. In the instance here reported, the large size of the upper tumors, the progressive diminution in size of the lower ones, as well as the insidious onset, seem to us to point to a primary neoplasia in this part of the intestine. While it is true of melanomas that the primary lesion may be small and the metastases huge, usually there is either a definite history of a previous removal of a primary growth or the evidence of such a lesion at the time of autopsy, none of which were traceable in this case.

SUMMARY

Multiple primary melanotic tumors (64 carcinomas (?)) of the small intestine were found in a man 35 years of age with the development of symptoms 9 months before death. Metastases occurred in the intestine, mesenteric lymph nodes and the heart. There being no other clinically or pathologically demonstrable primary source, it is assumed that the tumor started here from a possible mesoblastic type chromatophore.

Beriberi Due to a Reducing Diet*

By

MAURICE SNYDER, M.D.

SALINA, KANSAS

UNUSUAL interest in the *rôle* the vitamins play in health and disease has been exhibited in recent years. Although much has been said about the commoner deficiency diseases, little recognition has been given to deficiency states resulting from a lack of the vitamin "B" accessory food factor.

Up until the time when Strauss (1), in 1935, showed alcoholic neuritis to be directly due to a vitamin "B" deficiency, true "B" avitaminosis, or beriberi was considered of comparatively rare occurrence in the United States. Following is the report of such a case, a patient who suddenly developed generalized edema, *following a prolonged reducing diet, deficient in* vitamin "B."

REPORT OF CASE

The patient, a lawyer, aged 27, was seen first in the Cleveland Clinic, on February 6, 1932. Medical advice was sought because of sudden increase in weight, accompanied by swelling of the face and legs. The illness had begun one week before admission when the patient first had noticed a swelling of his abdomen and legs which had appeared rather suddenly. The patient found that he had gained eleven pounds in weight over a period of three days; at the end of a week he had gained sixteen pounds. The swelling increased in proportion to the increasing weight, and always was worse in the mornings, tending to decrease towards mid-day. On several occasions the patient had awakened in the morning with his eyes swollen completely shut. His only other complaints were of a feeling of discomfort in the lower chest and upper abdominal region, of some weakness and of loss of "pep." There were no genito-urinary symptoms until about two days before his admission when he had noted some frequency and since then had been voiding an unusually large quantity of urine.

On questioning the patient it was found that he had been on a very restricted, poorly balanced diet for the last year and a half. In January, 1930, numerous furuncles, scattered over his entire body had developed. These had proved very resistant to treatment and his physician finally had advised a diet in which starches, sugars and fruits were prohibited. The patient had existed on a grapefruit and a small portion of meat (beef) each day with a little lettuce once or twice a week. After dieting in this manner for about six weeks, the boils had disappeared and the patient had lost about 25 pounds in weight. He felt so much better with his weight reduced, that he decided to continue on this diet, which he carried out with very little variance for a total period of a year and a half. After dieting for a few months, he soon lost his appetite and had no desire for food. During the entire period his weight had been reduced from 165 pounds to 105 pounds. His weight was maintained for three to four months at 105 to 110 pounds, when edema supervened.

When seen by us, the patient weighed 127 pounds and his height was five feet, three inches. The skin and mucous membranes appeared healthy. The eye examination revealed nothing abnormal; the tonsils had been removed and there was no evidence of oral sepsis. The thyroid was not enlarged and there were no palpable glands in the neck. There was a general puffy appearance of the face, most marked in the tissues around the eyes. The chest was symmetrical, the lungs clear, and no pleural effusion could be demonstrated. The heart seemed normal in size and no murmurs or arhythmia could be demonstrated. The skin over the pectoral region was very loose and edematous; palpation showed the existence of pockets of fluid between the skin of the chest wall and the underlying subcutaneous tissues. There was diffuse edema of the abdominal wall similar to that found in the chest. There was no evidence of ascites. The external genitalia were entirely normal, without any evidence of edema. The legs, ankles and feet showed a moderate amount of edema which pitted deeply on pressure. All superficial and deep reflexes were normal. There was no evidence of arteriosclerosis. No muscular atrophy or weakness could be demonstrated; there were no sensory disturbances, and the Jongkok test was negative.

The pulse rate was 60 and the blood pressure was 100 systolic, 64 diastolic. The blood count showed 4,400,000 erythrocytes, 7,250 leucocytes, and the hemoglobin, 84 per cent. The blood sugar was 77 milligrams per hundred cubic centimeters one hour after a meal. The level of the urea in the blood was 24 milligrams per cent. The results of the urinalysis were negative except for a low specific gravity, 1.010. The Wassermann and Kahn tests were negative. Roentgenographic studies of the gastro-intestinal tract revealed pylorospasm and a very large, atonic colon.

COMMENT

The information obtained from the physical examination and from the routine laboratory tests was sufficient to rule out the presence of any of the diseases commonly producing edema. The history of a low caloric intake over a long period of time, which had

*From the Mowery Clinic, Salina, Kansas.
Submitted June 8, 1936.

resulted in marked loss of weight, anorexia and weakness followed by the rather sudden onset of edema, immediately raised the question as to whether or not this might be a case of so-called inanition edema. It was felt that the condition might easily be a vitamin "B" deficiency disease, that is, a "wet form" of beriberi in which the neuritic symptoms were absent or masked by the edema.

The rather unusual features of the case prompted further studies. The plasma protein, carbon-dioxide-combining power of the plasma, and the inorganic constituents of the blood were checked with the following results:

Serum Proteins	6.74	per cent
Serum Albumin	3.97	per cent
Serum Globulin	2.77	per cent
Cholesterol	150	mg.
Sodium Chloride	577	mg.
Phosphorus	3.5	mg.
Calcium	9.7	mg.
Urea	24.0	mg.
Uric Acid	1.7	mg.
Non-Protein Nitrogen	22.4	
Carbon Dioxide Combining Power	57.6	
Basal Metabolic Rate:		
Dubois	—23	per cent
Sanborn	—26	per cent
(Based on 116½ pounds)		
Phenolsulphonephthalein:		
First hour	30	per cent
Second hour	35	per cent
Urea Clearance	67	per cent

Comment. The plasma proteins in which we were most interested, were entirely within normal limits as were the carbon-dioxide-combining power of plasma and the inorganic constituents of the blood. The basal metabolic rate was rather low but this is to be expected in patients with edema. The edema in this case could not be explained on the bases of low osmotic pressure of serum proteins, as is found in inanition edema; and hence it was felt that it must be closely related, if not identical, with the edemas which occur in the wet types of beriberi. Although there were no neuritic symptoms in this case, it has been repeatedly shown that "ship" beriberi, a wet form of the disease, is a deficiency disease in which nervous phenomena are rarely present and that edema of various degrees is the predominating, oftentimes the only, physical finding.

COURSE

The patient, thoroughly alarmed about his condition, was quite willing to co-operate, and to dispense with his past dietary regimen. He was given a diet with a high vitamin, and low carbohydrate content, with a supplementary supply of vitamin "B" in the form of a concentrated vitamin "B" extract.

His response to this form of treatment was most satisfactory. The edema disappeared rapidly. In a weak he had lost ten pounds, his appetite had returned to normal, and he felt indeed much improved. The edema had entirely disappeared from his face, but was still evident in the pectoral region and in the lower extremities. He was advised to continue the treatment and to return at weekly intervals for observation. Edema continued to decrease and there was a gradual loss in weight, so that at the end of three weeks, there was no evidence of any gross edema. He had lost 16 pounds, undoubtedly due to the loss of fluid, in fact the amount of fluid lost was probably even greater than would appear from the figures, as most likely he had gained actually on the more substantial diet. The patient then began to gain, hoping to reach and maintain his weight at a level between 125 and 130 pounds, the proper amount for a man of his stature. Simultaneously with the disappearance of the edema there was a very marked increase in the urinary output.

In June, 1932, after having been free from symptoms for four months, the patient returned because of a reappearance of the edema. He had gained ten pounds rather suddenly and had had a very scanty output of urine. These symptoms occurred while the patient was on a three weeks' business trip, during which time he had stopped taking the vitamin "B" extract. The edema appeared almost two weeks after the extract was discontinued. An analysis of the serum proteins was done at this time and was found to be entirely normal. (Serum proteins, 8.32; albumin, 4.74; globulin, 3.58). Curiously enough, ten days after treatment with vitamin "B" was reinstated, the edema had entirely disappeared and the urinary output had returned to normal. The patient has remained well to the present time; however, he still is taking a liberal supply of vitamin "B" daily along with the proper diet. Subsequent examinations failed to show any evidence of peripheral neuritis. Repeated urine analyses during the period of observation showed no evidence of renal damage.

With the marked amelioration of symptoms and entire disappearance of edema on a high vitamin "B" diet, without the aid of other therapeutic measures, it was felt that this case was indeed one presenting the clinical picture and course of wet beriberi.

DISCUSSION

Although vitamin "B" is quite widespread in the animal and vegetable kingdom, we know that beef, lettuce, and fruit juices, which constituted this patient's diet, contain relatively small amounts of it, and when the diet is otherwise deficient, large amounts of these foods must be consumed in order to prevent the development of a deficiency disease. Vedder (7), in an excellent monograph on this subject stated that experimental work on beriberi, has demonstrated that the body is unable to store up much reserve vitamin. The depletion period as shown by various human feeding experiments may occur in man within 7 to 120 days. In the patient under discussion there were no symptoms for about a year and a half; the patient apparently feeling perfectly well until the sudden onset of edema and weakness caused him to seek medical advice.

The cause of edema in beriberi always has been obscure. McCollum (2) expresses the opinion that protein shortage is the probable cause of starvation dropsy and that wet beriberi may be an expression of two specific dietary lacks, protein starvation and deficiency of vitamin "B." With the discovery that plasma proteins are reduced in cases of nephrosis and other edemas it was thought that some light might be thrown on the mechanism of the production of edema in beriberi. However, no confirmatory reports are to be found in the literature. Kabayaski (3) reported the serum proteins normal in beriberi while Shigeari (4) and associates observed low values during the

edematous stages which rose to normal or above after the disappearance of the edema.

Nakazama (5) and co-workers reported a serum albumen values seldom below 4 per cent and colloid osmotic pressure of only one per cent below normal. They found the molecular weight of albumen greater in the edematous forms and suggest the hypothesis that the blood building mechanism is disturbed in beriberi. McCarrison (6) found that the adrenals of fowls suffering from "B" avitaminosis are considerably enlarged, and that the secretion of adrenalin by these enlarged glands is proportionally increased. He suggested that the edema may be due to circulatory changes resulting from this increased secretion of adrenalin. Vedder (7) stated that there is considerable experimental evidence to indicate that two vitamins are deficient in the diet that produces beriberi and suggested the possibility that the deficiency of one, the anti-neuritic vitamin, produces degeneration of the nervous system and the symptoms of dry beriberi, while deficiency of the second vitamin produces generalized edema and the syndrome, wet beriberi. Sargent (8) pointed out that in the wet form of beriberi an affection of the vasomotor nerves produces edema while in the dry form paraplegic manifestations are produced and palsy and atrophy of muscles occur.

The instance cited illustrates well one of the dangers encountered in the use of "reducing diets" without proper medical supervision.

SUMMARY

A young man exhibited generalized edema and weakness following a generally inadequate diet, deficient in vitamin "B." Laboratory tests, including a study of the plasma proteins and of the inorganic constituents of the blood were entirely normal. The complete disappearance of the edema and general symptoms, after a course of treatment consisting of the administration of vitamin "B" and an adequate diet, is proof that the condition was a deficiency disease, a "B" avitaminosis or wet beriberi.

ABSTRACTS

EXPERIMENTAL PHYSIOLOGY

COLP, R.

Biliary Duodenal Intubation. S. G. O., Vol. 62, No. 2, pp. 157-163, Aug., 1936.

In the author's opinion biliary duodenal intubation is a valuable procedure which should be applied in a greater variety of conditions. In addition to its use in cases of stricture or division of an extrahepatic bile duct he recommends it in any case in which external biliary drainage is undesirable, or one in which internal biliary drainage is imperative.

Many persons become markedly debiliated from prolonged loss of bile.

Another indication for biliary duodenal intubation is in the treatment of choledochal cysts. It seems questionable whether this procedure is preferable in cases of stricture near the porta hepatis in which the distal segment of the duct cannot be found. The author feels that it is perhaps better to transplant a firm fistulous tract into the stomach or duodenum.

In selecting the tube to be used the author recommends the best grade of rubber tubing, which, at the same time, is radiopaque. While a soft and pliable tube is essential it must be sufficiently rigid to maintain its lumen against external pressure in spite of ample fenestration. The tube should be large enough to fill the choledochus and fit snugly within the narrowed and spastic area of the papilla. It should be introduced from 8 to 10 centimeters down the duodenum and left so or anchored with a silk suture.

Five figures and four case reports accompany the article.

Nelson M. Percy, Chicago.

MOON, VIRGIL H., AND MORGAN, DAVID R.

Experimental Pulmonary Edema. Arch. Path., 21:5, p. 565, May, 1936.

The authors have studied experimentally pulmonary edema in dogs the result of (1) muscle implanted in the peritoneal cavity, (2) burns, (3) intestinal obstruction, (4) the intravenous injection of bile and of sodium glycocholate, (5) sodium phenobarbital, and (6) histamine. The type of edema produced in the lungs by each of the above intoxicants was characterized by a protein content approximating that of the blood plasma and a high specific gravity. This is in contrast to the edema occurring in nephrosis or dietary deficiencies which has a low protein content and a low specific gravity.

The above form of pulmonary edema results from increased vascular permeability and is accompanied with hemoconcentration (as much as 30 per cent increase, in some instances, of red blood cells per cmm. and grams of hemoglobin per 100 c.c. of blood) and with circulatory inefficiency. The mechanism of such edema is integral with that of the shock syndrome. The degree of edema found is less when a fatal shock develops rapidly, but when a few days elapse before death occurs it is found to be extensive and a common type of terminal pneumonia is found with it.

The acute congestion which precedes this type of edema as an accompaniment of shock resembles in appearance passive congestion. Its differentintion from the latter is to be discussed in a subsequent report.

GAITHER, ERNEST H.

Recent Advances in Gastro-enterology: Chairman's Address. J. A. M. A., Vol. 107, pp. 549-552, Aug., 1936.

One of the most stimulating recent publications is the monograph by Faber, in which he clearly sets forth his own views and those of other eminent authorities as to proofs of the presence and frequency of both acute and chronic gastritis. He has tried to show the relationship of acute and chronic gastritis to superficial and deep ulcerations; chronic gastritis and its tendency to

precede ulcer and carcinoma; and the relationship which hyperacidity and anacidity bear to these conditions.

Bloomfield and Polland published a monograph termed "Gastric Anacidity" which reports their research work on the secretory function of the stomach.

Castle's demonstration of the etiology of pernicious anemia is undoubtedly one of the most brilliant contributions of recent years. Hollander has also done some work concerning the composition of gastric juice.

Greengard, Maison and Ivy have isolated a substance known as enterogastrone, which inhibits gastric secretion and motility in the dog. Dragstedt has written an article on acute dilatation of the stomach which is valuable to internist as well as surgeon. Rehfuss has written "Medical Treatment of Gall Bladder Disease" while Lyon has done valuable work on gall bladder drainage.

The flexible gastroscope has been introduced and is expected to greatly increase the knowledge of gastric pathology in a few years.

Clasen and Eusterman have recently published some very excellent work on syphilis of the stomach.

Gastro-intestinal pain has been ably dealt with as regards localization, genesis, and probable pathways, by such men as Christensen, Boyden, Rigler and Rivers. Rowe, Duke and Vaughan have made splendid progress in allergic manifestations and gastro-intestinal disease.

The etiology of gastric ulcer is still in the theoretical stage, while Sippy and Smithies have done much in the treatment of the condition. Sara Jordan has done excellent work in the treatment of peptic ulcer.

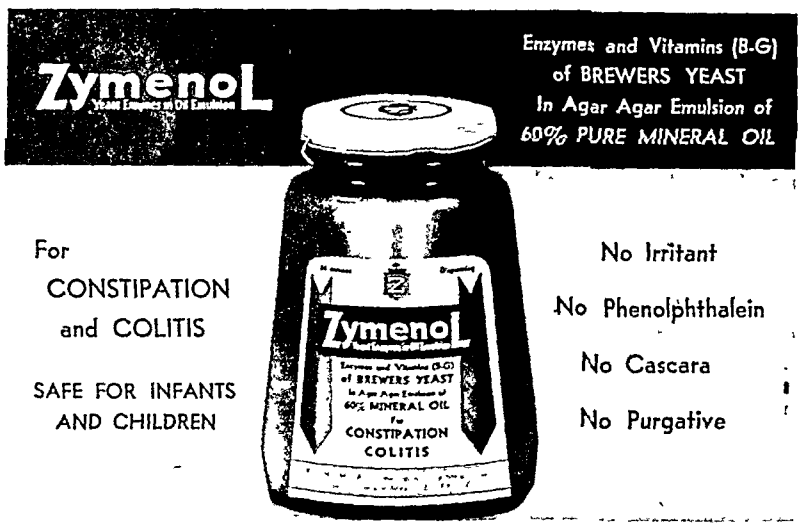
Miller and Gray have done work on the intubation of the small intestine and have studied the influence of organic and inorganic acids on the motility of the small intestine.

Crohn presents a splendid piece of work, "Regional Ileitis" claiming the discovery of a new disease entity. Felsen claims that this condition and *chronic idiopathic ulcerative colitis are* the end results of bacillary dysentery. Barren claims that ulcerative colitis is due to a specific organism and reports successful treatment with vaccines and serum. Sullivan has also studied the psychogenic factor related to ulcerative colitis.

Ivy has isolated cholecystokinin, a substance which has a specific action on the gall bladder. The function of the liver may be studied by such tests as the van den Bergh, coagulation time, sedimentation, galactose tolerance, bronisulfalein, rose bengal, Takata-Ara, and the hippuric acid test.

The Enzyme Committee of the American Gastro-enterological Association presented various reliable methods for the study of enzymatic activity. They came to various conclusions, too numerous to enumerate in this brief review.

The effect of a diet rich in carbohydrate has been shown by L. R. Brown to bear some relation to the etiology of migraine.



Dr. Madge T. Macklin has emphasized and demonstrated the importance of hereditary factors in gastro-intestinal disease.

Many advances have been made in radiologic diagnosis of gastro-intestinal disease, among the most important of which is Kantor's "Colon Studies" and Schotzki's work on the diagnosis of small ulcerative lesions and the gastritides. Cholecystography has also been greatly improved by the use of an oral dye. Excellent work has also been done in anomalies of the esophagus, especially the congenitally short type.

EFFERVESCENCE

A More Acceptable Form of Medication

Palatability and better toleration are secured when otherwise disagreeable medication is administered in effervescent form.

Three standard types of medication are here offered in the form of effervescent tablets:

Aspir-Vess

Provides the effervescent factor and alkalis added to a therapeutic dose of aspirin.

Bromo-Vess

The well known three bromides plus ½ minim Fowler's solution as a protection against bromide rash where large doses are used.

Cinsa-Vess

The antirheumatic agents—cinchophen, sodium salicylate, colchicine—and sodium bicarbonate with citric acid to insure a palatable, alkaline, effervescent solution.

EFFERVESCENT PRODUCTS, INC. • *Elkhart, Indiana*

Recently work was published which indicated that the odor might arise from particles of onion or garlic retained in the structures of the mouth.

Because of the controversy caused by the aforementioned theories, the following experiments were carried out. Garlic in one form or another was fed to three patients, one who had a gastrostomy fistula because of a carcinoma of the esophagus; another who had a tracheotomy fistula because of a cancer of the larynx; and the third, a boy who had a tracheal fistula because of a stricture of the larynx. In all of these cases the odor of garlic appeared on the breath, and in none of the cases was it due to the particles left in the mouth. When chloramine was given as a mouth wash, the odor disappeared for only thirty to sixty minutes. From the above results, the conclusion was reached that garlic breath odor is due to substances carried in the blood.

VI-SYNERAL
TRADE MARK
BRAND OF
Vitamins and Minerals
FUNK-DUBIN

REMOVES *the* DANGER
in RESTRICTED DIETS

Pointing to the fact that one of the causes of vitamin deficiency diseases are restricted diets, and that many cases therefore have specific needs for both vitamin and mineral protection, Charles L. Hartsock, M.D., in his recent paper, "The Role of Deficiency Disease in Diseases of the Gastrointestinal Tract" (Review of Gastroenterology, 3:111, 1936), states: "In practically every disease or functional disturbance of the gastrointestinal tract, some type of restricted diet is prescribed by the physician or voluntarily observed by the patient."

Restricted diets indicated in intestinal ulcers, diabetes, obesity, kidney, liver, gastric and many other disturbances, often contribute to the onset of deficiency diseases because of the limited intake of food. Complications develop in these cases which may be more serious than the original ailment.

Dr. Casimir Funk (Father of Vitamin Therapy) and Dr. H. E. Dubin, (his collaborator), after years of extensive nutritional research make available to the profession

VI-SYNERAL

containing the important health-giving factors that are absent in the average restricted diet, viz. all the food Vitamins, A-B1-B2(G)-C-D-E, and the Essential Minerals, Calcium, Phosphorus, Copper, Iron, Iodine, Manganese, Magnesium, Zinc.

VI-SYNERAL contains scientifically balanced potencies in safe and sound dosage. It is without bulk, calories, non-irritating, non-allergic.
Nutritional deficiencies are multiple and should be treated with multiple vitamin and mineral therapy.

VI-SYNERAL removes this great danger in restricted diets by supplying the essential elements.

SCHIODT, E.

Blood Regeneration in Patients with Hematemesis or Melana from Peptic Ulcer, Treated with the Usual Ulcer Cure and with the Menlengracht Treatment. Amer. Jour. Med. Sci., p. 163-167, Aug., 1936.

In July, 1931, Melengracht altered the treatment of patients with hematemesis or melena in this department. Previously such patients were given the usual "ulcer cure." Instead of waiting about four weeks for the establishment of the "puree diet," he gave it from the first day of admission, which often meant the first day of bleeding. This is a well balanced diet which includes meat, fish and vegetables, fruit, potatoes, in fact all sorts of food, finely minced in the form of force meat, mashed potatoes, pureed vegetables, fruit soups, jellies and so on. Lactate of iron and an aperient such as cascara were also given. A careful comparison study was made of 10 patients on the old "ulcer cure" and 10 patients on puree diet and iron. The patients on "ulcer cure" regenerated both red blood cells and hemoglobin much more slowly and less completely than did those on the puree diet and iron. In the latter cases the red blood cells and hemoglobin rose more nearly together, the color index being higher about 1., than in the ulcer cure group. The cases starting with r.b.c. 2.5 million and hgb. 50% on a puree diet with iron showed a rise in 30 days to 4 million red blood cells and 80% of hemoglobin, whereas, those on ulcer cure, with the same start reached only about 3.2 million r.b.c. and hemoglobin 55% in 30 days; a low color index all the way. The patients on the more abundant diet felt subjectively better and their clinical improvement was obvious to both doctors and nurses.

SYDENSTRICKER, V. P., ARMSTRONG, E. S., DERRICK, C. J., AND KEMP, P. S.

On the Existence of an Intrinsic Deficiency in Pellagra. Am. Jour. Med. Sciences, p. 1-9, July, 1936.

Method. Five patients were maintained on the original Goldberger-Wheeler pellagra-producing diet to which was added 25. gm. of fat salt pork. Gastric juice was obtained from normal medical students and from patients with no gastro-intestinal disease. To obviate the probability of increased gastric digestion of food, all doses of gastric juice were administered in the evening some 4 hours after the evening meal.

After reporting 6 cases in detail the authors suggest that there is an intrinsic factor present in normal gastric juice which makes possible the utilization of minimal amounts of extrinsic factor. (B2). Prolonged remission in two instances indicates that this intrinsic factor may be stored in the body. The hypothesis is advanced that in

Convalescents Require the High-Caloric Diet

Whooping Cough	2nd Week	Until 4 weeks from onset whoop

From American Journal of Public Health—March, 1927

INFECTIOUS FEVERS deplete the child's vitality. It is an exhaustion comparable to fasting. Convalescent children show a low metabolism for several weeks following the disappearance of the fever. The low metabolism is the consequence of generalized cellular damages.

When the infection clears, activity is curbed and rest periods instituted. The child is ready to gain. The problem is to bring about sufficient intake of food. The initial diet consists of small portions of each food prescribed and the amounts are gradually increased.

The high caloric diet is indispensable. It is made possible by reinforcing foods and fluids with Karo. Every article of the diet can be enriched with calories. A tablespoon of Karo provides 60 calories. Karo is relished added to milk, fruit and fruit juices, vegetables and vegetable waters, cereals, breads and desserts. Karo consists of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor), not readily fermentable, rapidly absorbed and effectively utilized.

ACCEPTED AMERICAN MEDICAL ASSN. Council on Food

Corn Products Consulting Service for Physicians is available for further clinical information regarding Karo. Please Address: Corn Products Sales Company, Dept. DN-12, 17 Battery Place, New York City.

pellagra there is an intrinsic deficiency of variable degree. Some retain enough to recover on diets grossly deficient in Vitamin B_2; others regenerate it in the presence of an abundance of the extrinsic factor while some are totally lacking in it but may recover under substitution therapy or die of nervous or cardiac damage inflicted before therapy was started. Further, the intrinsic factor is exhausted or cannot be regenerated during prolonged deprivation of extrinsic factor.

Allen Jones, Buffalo.

ROENTGENOLOGY

JENKINSON, E. L.
Cholecystography. J. A. M. A., Vol. 107, pp. 755-757, Sept. 5, 1936.

Cholecystography, as brought forth by Graham, Cole and their co-workers, is quite generally accepted in determining whether or not the gall bladder is functioning normally. When done under the proper conditions, namely cooperation and control of the patient, there is practically no diagnostic procedure more accurate.

The patient should not be allowed to take any fatty food from the time of the ingestion of the dye until the films are obtained. The patient should also be instructed not to move during the exposure. Slight movement may frequently obliterate a normal gall bladder shadow.

Cholecystograms were made on ninety-five patients; forty-nine were females and forty-six were males. The average age was forty-two years, and all had gall bladder symptoms. Seventy of these were normal, twenty-two were pathological and three patients failed to retain the dye.

Of the twenty patients with a pathological response, eight or forty per cent showed a normal response after being treated medically with a high fat diet and dehydrochloric acid; two showed a normal response with stones in the gall bladder, and four showed a poor response with stones in the gall bladder; five showed no response on two or more occasions; one showed a normal response followed by nonfilling; and two showed variable responses.

From these results the conclusion was reached that operative intervention is not indicated unless one or more negative responses occur after medical treatment.

Francis D. Murphy, Milwaukee.

COLLINS, E. M., AND ROOT, J. C.
Elimination of Confusing Gas Shadows During Cholecystography. J. A. M. A., Vol. 107, No. 1, pp. 32-33, July 4, 1936.

Cholecystographic interpretation is most frequently confused by the presence of gas in the right side of the gastro-intestinal tract. Enemata have been tried as a means of abolishing this condition, but results have been poor. Because of this, pitressin has been tried in doses of one ampoule (10 pressor units) in those cases in which confusing shadows appeared in the right side of the abdomen. Additional cholecystograms are taken forty-five to sixty minutes after the pitressin has been given. Effective results were obtained in 82 per cent of the seventy-three cases; 75 per cent of the patients had one or more stools within 45 minutes of the injection and almost all the patients had mild, cramp-like abdominal pains. In some of the cases there was a drop in blood pressure, in some no change and in others a moderate rise.

VICHY CÉLESTINS

THE WORLD'S MOST FAMOUS NATURAL STILL ALKALINE WATER

VITAMIN UNITS AND STANDARDS

● The past five years have brought agreement between biochemists of the various nations as to suitable units and standards of reference for most of the vitamins essential to man. The practice of expressing the vitamin potencies of foods and other biological materials in terms of *International Units* is, therefore, fast becoming universal.

Believing that these units and the standards upon which they are based would be of interest to our readers, they have been tabulated and defined below (1):

Vitamin A

The reference standard is a solution of pure beta-carotene in an inert oil, of such concentration that one gram of solution contains 300 micrograms (0.300 mg.) of beta-carotene. The International Unit, or I.U., of vitamin A is the vitamin A activity of 2 mg. of this standard solution, or 0.6 micrograms of beta-carotene.

Vitamin B1

The reference standard is the concentrate produced from rice polishings, by a specified adsorption method, in the Medical Laboratory of Batavia (Java). The International Unit for vitamin B1 is the vitamin B1 activity of 10 mg. of this standard adsorption product.

Vitamin C

The standard of reference for vitamin C is a specified sample of pure levo-cevitamic acid (levo-ascorbic acid). The International Unit for vitamin C is the vitamin C activity of 0.05 mg. of this standard.

Vitamin D

The reference standard for vitamin D is a solution of irradiated ergosterol, prepared under specified conditions at the National Institute for Medical Research (London). The International Unit for vitamin D is the vitamin D activity of 1.0 mg. of this standard solution.

These International Units for expressing vitamin contents have been specified in the most recent Pharmacopoeia of the United States (2) as well as by the Council on Pharmacy and Chemistry (3) and the Council on Foods of the American Medical Association (3), and provision has been made for distribution of the standards in this country (4).

These units have been used to express vitamin potencies in recent studies on canned foods, the results of which further emphasize the fact that these foods rank among the most important sources of the vitamins essential in human nutrition (5), (6), (7).

This is the nineteenth in a series of monthly articles, which will summarize, for your convenience, the conclusions about canned foods which authorities in nutritional research have reached. We want to make this series valuable to you, and so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

monia, acute fibrinous pleuritis, coronary thrombosis, acute fibrinous pericarditis closely resemble, at times, the "acute surgical abdomen." Disease of the abdominal structures may be simulated by osteomyelitis of the thoracic vertebrae, intercostal neuralgia, etc. Acute cardiac decompensation with sudden hepatic engorgement, ruptured or dissecting thoracic aneurism, pulmonary infarct, acute mediastinitis and spontaneous rupture of the oesophagus may mimic primary abdominal disease. The authors found only four reports of spontaneous pneumothoracic simulating primary abdominal disease in the medical periodical literature. The authors observed three cases and attribute their detection to frequent resort to the Roentgen ray in questionable abdominal conditions. The cases found in the literature are described and then author's cases. In comment, attention is directed to the difficulty of diagnosis because intense abdominal pain, nausea and vomiting, associated with tenderness and rigidity which were present in the cases recorded, constitute a syndrome which generally demands immediate laparotomy. The error of regarding a sudden pneumothorax as an abdominal lesion can almost invariably be avoided, the authors write, by a careful chest examination of each patient with an atypical picture of abdominal disease. The Roentgen ray is of extreme importance. A small amount of free air is difficult to identify unless fluid is simultaneously present in the chest cavity. Sudden pneumothorax simulates ruptured peptic ulcer so Roentgen ray serves a double purpose.

Many years ago I read a paper at a meeting of the American Medical Association entitled "Abdominal Symptoms of Thoracic Disease" so this valuable contribution by the above authors interests me very much.

Allen Jones, Buffalo.

POSITIVES and NEGATIVES

GENTLE LAXATION
NATURAL MOVEMENT
EASY TO TAKE

NO LEAKAGE
NO DISCOMFORT
NO GRIPING

A creamy, pleasant-tasting emulsion of Genuine Phillips' milk of magnesia and pure mineral oil, which meets all the requirements of a safe, regulative laxative.

FORMULA:

Each tablespoonful contains —
Genuine Phillips' Milk of Magnesia 5iii
Finest Quality of Mineral Oil 5i

Supplied in 8-oz., 16-oz., 32-oz. bottles

BRODY, HENRY, AND SMITH, L. W.

The Visceral Pathology in Scarlet Fever and Related Streptococcus Infections. Am. Jour. of Path., 12:3, p. 373, May, 1936.

The authors present a study of the visceral pathology in scarlet fever and related streptococcus infections. It is based upon the histological examination of material from 44 frank cases and 15 presumptive cases of scarlet fever. They believe the underlying lesion is one of vascular injury with a concurrent, perivascular round cell infiltration. These lesions were found widespread throughout the visceral organs, particularly constant in the hearts, livers, kidneys, adrenals and spleens of these cases. They believed the lesions were probably due to a circulating toxin, for in no instance were they able to demonstrate microorganisms in stained sections. In most of the cases hemolytic streptococci were obtained in blood and tissue cultures. The interstitial mononuclear lesion is not considered specific for scarlet fever. It is seen in other infectious diseases when associated with streptococcic infections, notably diphtheria and measles, although less widely disseminated and less frequently found than in scarlet fever. Its frequency in many organs in scarlet fever, however, and the similarity of its appearance in the various organs, suggest the fundamental importance of the lesion in the pathology of this disease.

Authoritative Digest of Scientific Literature on the Banana

"Nutritive and Therapeutic Values of the Banana—A Digest of Scientific Literature" is the title of a new publication offered to you free on request. It has been prepared with the object of enabling the busy physician, as well as the dietitian, to become quickly yet thoroughly acquainted with the published facts regarding the nutritive and therapeutic values of the banana.

This digest, in the form of an annotated bibliography, embraces both articles and books, including English translations of literature originally published in other languages.

You may secure a copy without cost or obligation. Simply fill in and mail the coupon below.

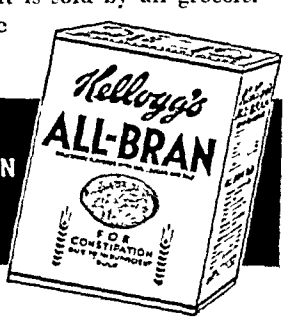
INTERNAL EXERCISE



WITH millions of men, golf, riding and other forms of exercise are a daily ritual. In fact, as doctors know, they may overdo it. Yet these same men eat meals that fail to give their systems proper exercise, meals that may lead to common constipation due to insufficient "bulk."

Fruits, vegetables and bran are the best sources of "bulk." But experiments have indicated that, with some individuals, the "bulk" in fruits and vegetables is largely broken down in the intestines. So bran is often more effective.

Kellogg's ALL-BRAN is an excellent source of gentle "bulk." Scientific tests show that it is safe and effective. Within the body, this "bulk" absorbs moisture, and forms a soft mass. Gently this exercises and strengthens intestinal muscles, and cleanses the system. ALL-BRAN also supplies vitamin B and contains iron.

This natural laxative food may be served as a cereal with milk or cream, or cooked into appetizing muffins, breads, etc. It is sold by all grocers. Made by Kellogg in Battle Creek.

The natural food THAT CORRECTS CONSTIPATION due to insufficient "bulk"

cases had preliminary colostomy established. All three stomach cases had a jejunostomy done for the purpose of feeding during the course of the treatment. The rectal growths were accessible through a proctoscope. Since the stomach must be kept open for an interval of three to six weeks to allow the proper time interval between the two or three necessary treatments temporary closure is obtained by the use of a zipper or a rubber patch.

The progress of the pathological lesion in its response to this type of treatment is described in some detail. There is first excavation, then appearance of edematous jelly-like tissue, absorption of this tissue, and connective tissue formation with occasional contraction but usually softening of the tissue. The excellent results reported are attributed by the authors not only to the simple mechanical destruction of the cancerous tissue but also to the liberation of certain substances which are absorbed in the body in general. These substances are believed to stimulate the reticulo-endothelial tissues and macrophages which not only prevent further growth but also help to destroy the growth present. These effects seem applicable to the regional lymph nodes and probably the liver as well.

It is interesting to speculate upon the possibilities suggested by this type of treatment and the reaction obtained in malignant cells.

ABDOMINAL SURGERY

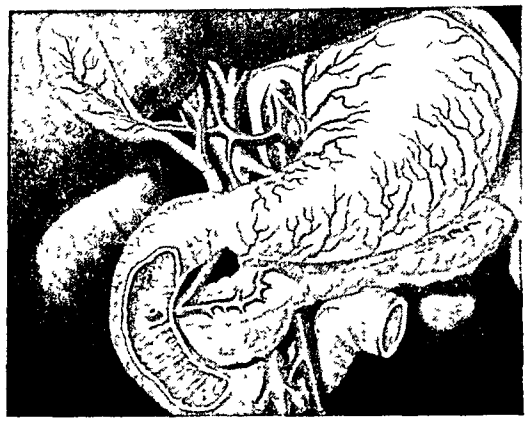
PRIESTLEY, J. T., AND MCCORMACK, C. J.

Generalized Peritonitis Secondary to Rupture of the Appendix. With Special Reference to Serum Therapy. S. G. O., Vol. 63, No. 5, pp. 675-680.

In the treatment of acute appendicitis the authors prefer the Ochsner type of treatment for those cases with generalized peritonitis. Immediate operation is favored in all cases in which rupture has not occurred, and in certain cases in which rupture has occurred. If rupture has occurred recently, and peritonitis is not advanced, operation is performed, but extreme care must be taken to prevent spreading the infection. If rupture occurred remotely, and the process seems to be held in check by the patient's natural defense mechanism, operation may be deferred until localization is completed. Operation may be advisable if a local peritonitis tends to become generalized while under medical management. If operation is performed in the presence of peritonitis, drainage should be instituted, and appendectomy may or may not be performed. If the appendix may be removed without traumatizing the already inflamed structures it should be done, but if it is not readily accessible it should be left in place and removed at a later date.

Routine bacteriologic studies in cases of appendicitis reveal a great variety of organisms. Most commonly aerobic cultures yield Escherichia coli and others, while anaerobic cultures yield Clostridium welchii and others. The theory has been advanced that the anaerobic organisms create a more favorable environment for the growth of streptococci and other aerobic organisms which are commonly considered to be the lethal organisms in peritonitis.

On the basis of those observations Weinberg has prepared three serums to be used as an adjunct to the surgical or medical treatment of acute appendicitis with peritonitis. The first is a polyvalent serum for the anaerobes commonly found in these cases. The second is a colon bacillus serum, while the third is a serum to combat any other organisms present.



The authors have used these sera in a number of cases, and are of the opinion that the method offers some hope of reducing the mortality of peritonitis secondary to rupture of the inflamed appendix. Certain of their patients, they believe, have been benefited materially from this serotherapy.

They recommend adequate doses given preferably within 24 hours of the onset of peritonitis. It is of value in more

Makers of Medicinal Products

PULVULES BILRON

(Iron Bile Salts, Lilly)

This new preparation has distinct advantages for administering bile salts when stimulation of the secretory mechanism of the liver is indicated.

Among the conditions for which 'Bilron' may be prescribed are noncalculous gall-bladder disease, dyspepsia due to hepatic insufficiency, gastro-intestinal-migraine syndrome, and in all cases where a disturbed gastro-enterohepatic circulation of bile salts is to be held responsible for impaired intestinal activity.

Pulvules 'Bilron' (Iron Bile Salts, Lilly) are supplied in 5-grain pulvules (filled capsules) in bottles of 40 and 500 through the drug trade.

STEINBERG, M. E.

The Surgical Treatment of Deep Seated Non-Resectable Ulcers of the Duodenum. S. G. O., Vol. 63, No. 5, pp. 625-631, Nov., 1936.

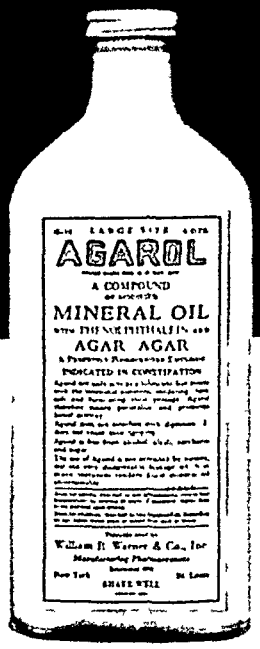
The author describes a new method of surgical treatment of deep seated ulcers of the duodenum. Proper and successful application of the method depends upon a thorough understanding of the principles involved and the technic employed. In certain cases in which anatomical anomalies or changes resultant from old inflammatory processes make the application of this method unsafe, the modified Finsterer exclusion operation may be performed.

In the author's technic the stomach is divided three finger breadths proximal to the pylorus and the proximal portion reflected to the left out of the way. Through the pylorus the duodenum is palpated, the ulcer located and its size determined. The anterior wall of the duodenum is now incised transversely along a line just proximal to the proximal border of the ulcer and reflected distally. A flap of the anterior duodenal wall sufficiently large to invert and cover the entire ulcer must be obtained; if this is not possible without tension, the duodenum would be closed and the modified Finsterer operation performed. The ulcer is now cauterized with phenol and alcohol, and the mucosa removed from its edges by means of a small currette. The free margin of the anterior duodenal wall is now sutured to the distal margin of the ulcer. Another row of sutures is now placed through the proximal margin of the ulcer and the serosa of the anterior duodenal wall inverted over the ulcer. The ulcer is thereby covered. The posterior duodenal wall and a portion of the posterior wall of the stomach from which the mucosa has been removed is now reflected over the closed duodenum and sutured in place. Finally the capsule of the pancreas is sutured to the closed end of the duodenum.

The author has used this method in three cases and recommends it because it precludes any injury to the common duct, pancreatic ducts, pancreas, or the blood supply of any of the structures involved.

Eight figures and a bibliography accompany the article.

Nelson M. Percy, Chicago.



BRUNN, H.

Acute Pelvic Appendicitis. S. G. O., Vol. 63, No. 5, pp. 583-592, Nov., 1936.

In an attempt to bring forcibly to the minds of the profession a certain form of atypical appendicitis in which the appendix is placed either on the brim of the pelvis, or deep in the pelvis, the author reports in detail several such cases and discusses some of the diseases which are most likely to be mistaken for it.

The most constant symptom is pain which, at the onset, does not differ particularly from that of any appendiceal attack. When localization takes place, it is more frequently on the left side than the right side in this type of appendicitis. Vomiting may or may not occur. Diarrhea may accompany the onset. Physical findings are atypical of appendicitis; there may be no tenderness even on deep palpation and no rigidity. The temperature may be normal. Irritation on urination is frequently a symptom which must be brought out on direct questioning. Examination of the urine will frequently show the presence of red blood cells when the appendix lies against the bladder or a ureter. The blood count, which is important, is usually high, 15,000 to 20,000, with a high polymorphonuclear

The FIRST SPOONFUL TO THE LAST . . .

Agarol is supplied in 6, 10 and 16 ounce bottles.

Uniformity of composition throughout is important in an emulsion. It assures uniform action from every dose. Agarol is such an emulsion of mineral oil and agar-agar with phenolphthalein. It pours freely as a good emulsion should. It mixes readily with liquids and stays mixed without "cracking."

In the relief of acute constipation and in the treatment of habitual constipation, Agarol affords proved efficiency, consistent reliability, combined with palatability that only purest ingredients can give without artificial flavoring. Let us send you a trial supply. Please ask for it on your letterhead.

AGAROL FOR CONSTIPATION

WILLIAM R. WARNER & COMPANY, INC., 113 West 18th Street, New York City

CLINICAL BACKGROUND

Creamalin

The Specially Prepared Colloidal Cream of Aluminum Hydroxide in

PEPTIC ULCER

Creamalin was released to the medical profession because of repeated demands by physicians who were acquainted with the results obtained when the product was in the investigative stage, several years ago. Subsequent usage in thousands of cases by competent clinicians has substantiated the early findings, and still more work is piling up further evidence.

On the basis of clinical results, Creamalin merits the clinical consideration of every physician who has occasion to treat gastro-duodenal ulcers. The producers will be pleased to supply a sufficient quantity of Creamalin for a critical clinical evaluation of this product, either by oral administration, or by the continuous drip method using the new Creamalin Automatic Drip Control. Correspondence is invited.

count. Rectal examination, properly done and repeated once or twice daily, will reveal tenderness in those cases in which the appendix is low in the pelvis.

During the second 24 hours there is a gradual rise in the temperature, the polymorphonuclear count will rise, and if a Schilling count is made a distinct shift to the left will be seen. If the disease progresses to rupture, the signs typical of an intra-abdominal calamity supervene.

The sedimentation rate which is markedly hastened in cases of salpingitis is the best differential point between the two conditions. Bleeding from a ruptured ovarian follicle presents a variable and changing picture. Roentgenograms will aid in differentiating ureteral calculi from pelvic appendicitis.

Two tables and some illustrative case reports with individual discussion accompany the article.

Nelson M. Percy, Chicago.

CHRISTOPHER, F.

Intussusception in Adults. S. G. O., Vol. 63, No. 5, pp. 670-674, Nov., 1936.

The author reviews the literature on intussusception in adults and reports two new cases. The etiologic agent most commonly recognized has been a tumor, either benign or malignant. In adults the symptoms are usually those of acute intestinal obstruction, but they may simulate cholecystitis or peptic ulcer.

One case of chronic ileocecal intussusception, and one of high jujunal intussusception due to a papillary adenoma, are reported.

Three figures and a bibliography accompany the article.

Nelson M. Percy, Chicago.

WOLFSON, W. L., AND ROTHENBERG, R. E.

A Simple Method of Amputating Exteriorized Bowel with the Carr Hilar Lobectomy Clamp. S. G. O., Vol. 63, No. 4, Oct., 1936.

In order to avoid the occasional complications following the secnod stage Mikulicz operation, the authors use and recommend the use of the Carr hilar lobectomy clamp. It is applied at the bedside about 36 hours after the operation, and usually falls off, or may be cut away, after 4-5 days. A small incision may be made in the distended bowel and a catheter inserted to allow gas and fecal matter to escape when distention becomes marked.

In the author's series of 5 cases no instance of hemorrhage, peritoneal infection, or other complications has developed because of the use of the Call clamp.

Three figures illustrating the use of the clamp accompany the article.

Nelson M. Percy, Chicago.

SENGSTACKEN, R. F.

Appendicitis in the Small Hospital. S. G. O., Vol. 63, No. 4, Oct., 1936.

The author reports the appendicitis experience since 1920 of a 42 bed hospital in a small community. A total of 602 cases of acute and purulent appendicitis were treated there during that time. The mortality rate was 2.98 per cent for total cases, 0 per cent for chronic, 3.4 per cent for acute and 15 per cent for purulent. Since 1930 it is still lower, viz., 2.1 per cent for total cases, 2.25 per cent for acute and 13.4 per cent for purulent cases. The Battle-Kammerer technique is followed; the stump of the appendix is inverted only in gangrenous cases. Drainage was employed in all pus cases. Ileostomy in the author's opinion should be used only as a secondary procedure but should be done before the small bowel is completely paralyzed. Cecostomy was not used in any case.

In the postoperative management the author feels that patients in small hospitals receive better treatment because they are seen by the surgeon rather than an interne. Sufficient fluid to keep the tongue moist, and repeated transfusions in seriously sick patients, are advised. For

postoperative distention pituitrin or pitressin are employed. If these fail, a duodenal tube is employed and small amounts of hypertonic saline are instilled into the stomach at 3 hour intervals.

The author concludes that in the treatment of appendicitis the small hospital is superior to its larger brother in the city in that the patients are attended by staff members and graduate nurses rather than internes and student nurses respectively.

Nelson M. Percy, Chicago.

ANNOUNCEMENT

BUREAU OF HUMAN HEREDITY

115, Gower Street, London, W. C. I, England.

The object of this Bureau is collection on as wide a scale as possible of material dealing with human Genetics. Later, the tasks of analysis of material and distribution of the information available will be added.

The Bureau is directed by a Council representing medical and scientific bodies in Great Britain. It is affiliated to the International Human Heredity Committee, which insures co-operation in all areas where research is proceeding.

The Council would be grateful to receive all available material from Institutions and individuals, furnishing well-authenticated data on the transmission of human traits whatever these may be. Pedigrees are particularly desired; twin studies and statistical researches are also relevant. As research workers and others who send in material may in some cases wish to retain the sole right of publication (or copyright) those who so desire are asked to accompany their material with a statement to that effect.

Material should be given with all available details in regard to source, diagnostic symptoms and the name and address of the person or persons who vouch for accuracy. All such details will be regarded as strictly confidential.

Reprints of published work would be most acceptable. Further, many authors when publishing material may also have collected a number of pedigrees which they have been unable to reproduce in detail. It is the object of the Council that such records, by being included in the Clearing House, should not be lost.

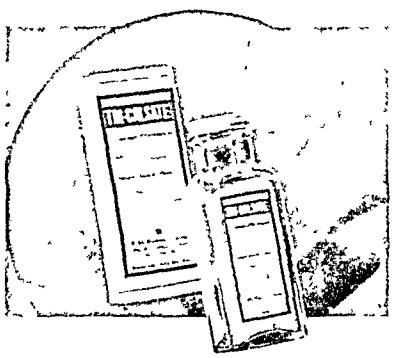
Those wishing for a copy of the Standard International Pedigree Symbols may obtain one from the office.

Announcement in regard to the services undertaken by the Bureau will be published from time to time.

Chairman: R. Ruggles Gates.

Executive Committee: R. A. Fisher, J. B. S. Haldane, E. A. Cockayne, J. A. Fraser Roberts, L. E. Halsey (Hon. Treasurer), C. B. S. Hodson (Hon. Gen. Secretary).

CONSTIPATION



FORMULA: Extract of the intestinal glands ..... 0.05 gr.

CLUTE, H. M.

The Problem of Cancer of the Pancreas. J. A. M. A., Vol. 107, pp. 91-97, July 11, 1936.

Recently the surgical removal of small tumors from the pancreas and tubtotal pancreatectomy has been reported. These procedures were carried out because of hyperinsulinism and results have been satisfactory.

Cancer of the pancreas is not a rare disease, constituting 4.8 per cent of the cancer deaths in Massachusetts hospitals in 1928 to 1930. On the whole it constitutes about 3 per cent of all cancer deaths in the United States.

The tumor is most frequently located in the head of the pancreas; some are diffuse, and a few are limited to the tail of the organ. They are generally adenocarcinomas, but scirrhous forms do occur. They metastasize in the usual ways, usually very early. Metastasis is to the regional lymph nodes, liver, lungs and pleura. The tumor as it grows may produce obstruction of the common bile duct and rarely hyperinsulinism and disturbance of intestinal digestion.

The earliest symptoms of cancer of the pancreas is a dull, boring, epigastric pain, digestive distress, epigastric fullness, abdominal distention, and a severe loss of weight in a short period of time. Rarely the first symptom is the onset of jaundice, but usually this, with a palpable tumor in the epigastrium, are signs of advanced conditions.

The diagnosis depends upon the absence of lesions in the gastro-intestinal tract, and the gall bladder as established by X-ray, with the presence of the aforementioned symptoms.

Treatment of the condition is most likely to be successful with surgery, although X-ray and radium have been tried with varying degrees of success. Desjardins and Suave, in 1907 and 1908, advocated a biliary intestinal anastomasis, a resection of the head of the gland and the duodenum, a reuniting of intestinal continuity, and finally the insertion of the pancreas or its duct into the intestine. Whipple, Parsons and Mullins followed this procedure except that they ligated the pancreatic ducts.

Francis D. Murphy, Milwaukee.

EGGERS, C.

Treatment of Carcinoma of the Esophagus. S. G. O., Vol. 63, No. 1, pp. 54-65, July, 1936.

Among the methods of palliative treatment of carcinoma of the esophagus the author mentions general medical care, in which the diet is regulated and balanced carefully; then Gastrostomy when swallowing becomes too difficult and other methods; namely, dilatation, intubation, radiation and electrocoagulation in selected cases with polypoid types of growth.

The radical surgical treatment encounters different problems when the growth is in the cervical, mid-thoracic or lower thoracic regions of the epophagus. Preliminary gastrostomy or jejunostomy is done in all cases.

In cases of carcinoma of the cervical portion of the esophagus with involvement of the hypopharynx and the larynx, complete extirpation of those structures, with their lymph nodes, is the operation of choice. That may be accomplished in a one stage or a two stage operation. In either case the esophagus and trachea open externally. The tracheatomy is permanent but the hypopharynx may be reconstructed later.

In cases of carcinoma of the thoracic portion of the esophagus, devised and first performed by Torck, has been followed with the greatest operative success. It is a transpleural procedure in which the esophagus is divided below the tumor and both ends closed, after which the tumor is delivered through a separate incision in the neck. If the patient survives the operation a rubber tube may be used as an esophagus or a subcutaneous esophagus may be reconstructed on the anterior chest wall.

In cases of carcinoma of the lower esophagus and cardia resection of the tumor mass and esophagus, gastristomy may be done through an abdominal incision or through an abdominothoracic approach as described by Kirchner.

Twenty-three figures and a bibliography accompany the article.

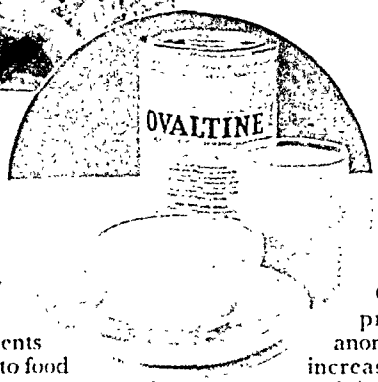
PACH, G. T., AND SCHARNAGEL, I. M.

The Technique of Gastric Resection for Carcinoma. A critical Review. S. G. O., Vol. 63, No. 2, pp. 189-197, Aug., 1936.



The authors review the history of gastric resection for carcinoma and follow the developments in technic from the original Billroth *I* and Billroth *II* procedures up to those now widely used. The first modifications were made by Schoemaher, Kocher and Haberer-Finney. Each one possessed certain advantages and disadvantages. Later modifications were made by Horsley and Mayo. In the author's opinion the Horsley operation possesses decided advantages over the other operations and in the hands of its master originator is suitable for the majority of carcinomas in the distal third of the stomach.

The Billroth *II* procedure, which made possible the resection of many more tumors of the stomach, has been modified in almost every possible way. The modifications proposed by Polya, Balfour, Moynihan and Finsterer and certain combinations of them are most widely followed today. Very little, in modern literature recommends the Roux, Kronlein or Mikulicz procedures. Sleeve resection of the stomach for carcinoma is rarely used. It is better judgment to excise the portion of the stomach distal to the superior line of excision and make an intestinal anastomosis. Cardiectomy has been performed

Have you a SPECIAL FEEDING PROBLEM?

There is an appetizing and nourishing food in a form readily tolerated by those in whom appetite and digestion are impaired.

When appetite and digestion are handicapped, the physician faces a problem of *special feeding*. Here are a few common situations in which doctors in special fields find it necessary to employ special feeding—

INTERNISTS frequently see patients with faulty starch digestion due to food bolting or deficiencies of salivary or pancreatic secretions. Elderly people and convalescents likewise have impaired digestion. There is a food of special value in such cases.

PEDIATRICIANS are often called to treat undernourished and underweight children in whom anorexia is present. Many times nervousness is correlated with undernourishment. In cases of this kind there is a food which has been very useful.

OBSTETRICIANS meet feeding problems in the nausea and anorexia of early pregnancy, in the increased demands of the developing young, and in the postpartum and nursing periods. There is a food of benefit all through this time.

SURGEONS have the special problem of building up patients before and after operation. In many cases they are called upon to supply appetizing nourishment in an easily digested liquid form. There is a food that may be of great help in such cases.

OVALTINE IS THE FOOD that meets these demands. It is appetizing and nourishing without overtaxing digestion. Its usefulness in special feeding problems is due to the following properties:

1. It offers concentrated food made from nutritious raw materials—barley malt, eggs, milk—specially processed to make it easy to digest.
2. It contains appreciable amounts of malt diastase to insure against faulty starch digestion.
3. Its addition to milk results in the production of finely comminuted, soft curd particles in place of tough curds.
4. It adds appreciable amounts of vitamins A, B_1 and B_2 (G). Its natural vitamin D content has been supplemented and standardized by the Steenbock Irradiation Process.
5. It contains the minerals calcium, phosphorus, copper and iron.

Doctor, *take advantage of the special offer below. It will enable you to test the merits of* OVALTINE. *Originated over 40 years ago, it has stood the test of time. Improvements have been made in the light of modern scientific knowledge. Clinical experience has proved its value when appetite and digestion are handicapped.* Try *it in* your *special feeding problems.*

so rarely that no uniform technique has been worked out.

Total gastrectomy has been performed in a number of instances. The reported mortality of the procedure is 53.8 per cent. Several recent improvements in technique have been made. Moynihan's suggestion that the esophagus be sutured to the jejunum before the stomach is removed has been widely accepted and used. In rare cases it is possible to anastomose the duodenum to the esophagus. When termino-lateral anastomosis between the esophagus and jejunum is effected a complementary enteroanastomosis should always be done between the ascending and descending limbs of the jejunal loop.

A bibliography and five figures accompany the article.

STEIGMAN, FREDERICK, AND SINGER, HARRY A.

Spontaneous Pneumothorax Simulating Acute Abdominal Affections. Am. Jour. Med. Sci., July, 1936.

The simulation of acute abdominal disease of a surgical nature by common and uncommon thoracic affections with referred pain and by lesions of the spine and spinal nerves is well known. No reference to pneumothorax simulating the "acute abdomen" was found in the American textbooks or systems of surgery, or in treatises dealing with abdominal or thoracic diagnosis, including continental sources, except by Adams, J. E. "Diagnosis and treatment of the acute abdominal disease," 2nd ed., London, Balliere, Tindall, Cox, 1923. In a careful search, only 5 references from the periodical literature since 1911 were found. Among the six instances reported therein, four spontaneous pneumothoraces were erroneously diagnosed primary abdominal disease.

The writers believe that the reported incidence of spontaneous pneumothorax simulating abdominal disease is lower than the actual because of their having seen three such patients in whom they made a correct diagnosis in a relatively short time.

A summary of four previously reported cases and a more detailed account of their own three follows.

Authors comments: Sudden pneumothorax furnishes difficulties in differential diagnosis from the acute abdomen, because the clinical picture of sudden rupture of the lung may be chiefly abdominal. Intense abdominal pain, nausea and vomiting, associated with tenderness and rigidity usually involve a decision as to immediate laparotomy. In four of eight reported cases a history of previous gastro-intestinal disturbance complicated the picture. The thoracic manifestations present in pneumothorax may be associated with acute surgical abdominal affections i.e. sudden pain following violent exertion, reference of pain to the shoulder region, dyspnea, collapse and assumption of the sitting position with the knees drawn upwards.

Error in diagnosis may be avoided by

1. Awareness of the symptom complex in pneumothorax.
2. Careful chest examination in atypical abdominal disease pictures. The detection of a pneumothorax requires expert physical examination.
3. Close attention to the abdominal examination, which may disclose the difference between the hyperesthesia of referred pain and the tenderness of abdominal disease.
4. Suspecting pneumothorax if a history of previous chest disease, especially tuberculosis, is obtained.
5. Routine roentgen examination. This is extremely valuable and quickly done. Unrecognizable and atypical pneumothorax, especially if partial, can best be detected by X-ray and on the film better than fluoroscopically, the latter especially when no pleuritic fluid is present. The exposure should be made at the height of forced expiration, when the pneumothorax becomes most apparent. The roentgen ray serves a double purpose, as it distinguishes a pneumoperitoneum, if present, and thereby aids in the diagnosis of ruptured peptic ulcer, which commonly needs to be ruled out because of its similar history and physical findings.

Marie Ortmayer, Chicago.

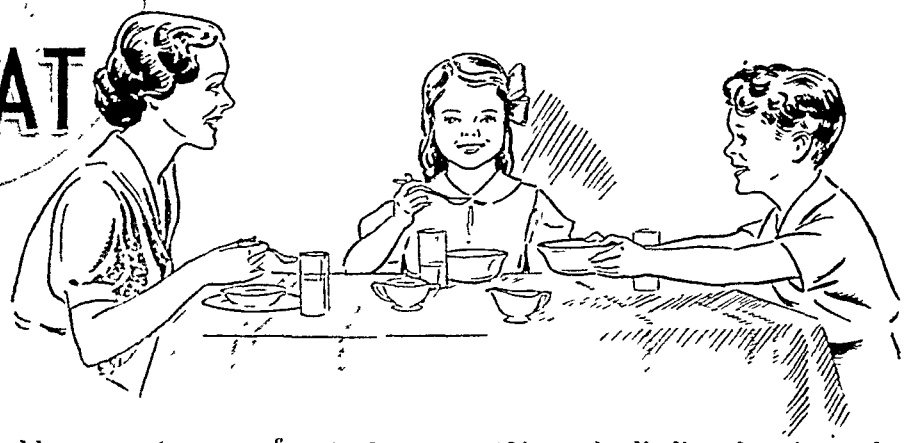
SURGERY OF THE LOWER COLON AND RECTUM

MACGUIRE, D. PHILIP.

"Palliative Colostomy." S. G. O., 63:66-68, July, 1936.

A recently reported mortality of 13.4 per cent in 500 cases of palliative colostomy shows that there is still much room for improvement in the handling of such cases. A new operation is described, which has for its outstanding characteristics a tongue shaped flap of skin and fascia extending medially from the center of the usual left inguinal incision, and a method of suturing the lateral peritoneal fold to avoid subsequent herniation and obstruction. An added advantage claimed is that immediate opening of the bowel can be done. Complete details of the preoperative, operative, and post-operative treatment of these cases is to be described in detail in a future publication. Local anesthesia and cyclopropane with the McGill intratracheal catheter are the methods of choice in producing anesthesia in these poor operative risks.

J. Duffy Hancock, Louisville.



APOLOGY

In the November issue, the address of Dr. Victor C. Meyers was printed at Palo Alto, California, whereas the correct address should have been Cleveland, Ohio.

ITS PALATABLE TASTE

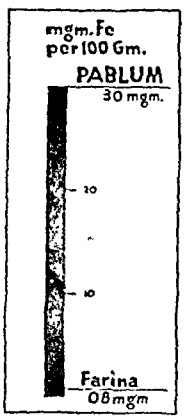
Adds Appetite Appeal to Nutritional Value

CREAM of WHEAT

Because of its palatable taste Cream of Wheat has made millions of friends in the homes of America. This appetite appeal is due not only to the careful blending of wheat from the various sections of America's grain belt, which year in and year out maintains the quality of Cream of Wheat, but also to definite constancy of size in the Cream of Wheat granules. There are no large particles which might break down less readily, nor small ones which might form a paste upon cooking. * * * * Cream of Wheat, prepared from the endosperm of the hard wheat berry by removal of the bran covering and the germ, ideally meets the requirements of a cereal for infants, growing children, and adults. It provides an abundance of essential food elements and minerals; the average analysis reveals: protein, 11.8%; fat, 2.4%; carbohydrate, 72.5%; and alkaline forming ash, 0.7%. Because of the high temperature used in its manufacture, and since it is devoid of bran, Cream of Wheat is quickly broken down by the amylolytic enzymes. Conversion to dextrose is rapid, as are subsequent absorption and utilization. * * * * These features, together with its palatability, make Cream of Wheat an ideal cereal for infant and child feeding, and a desirable, economical food for adults.

•

An interesting and informative brochure, "The Role of Carbohydrate Digestion and Metabolism in the Body Economy," will promptly be furnished to physicians on request. Please address The Cream of Wheat Corporation, Minneapolis, Minnesota, Dept D D.—12-36.



THE CREAM OF WHEAT CORPORATION

MINNEAPOLIS, MINN., U. S. A.

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.[1] "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embyro, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1,2] *Bibliography on request.*

The Value of Group Psychological Procedures in the Treatment of Peptic Ulcer

By

M. N. CHAPPELL, Ph.D.* J. J. STEFANO, M.D.†
J. S. ROGERSON
and
F. H. PIKE, Ph.D‡
NEW YORK, NEW YORK

FOR many years, the belief has been widespread among physicians that the emotional activity of the patient plays an important part in the maintenance of peptic ulcer, preventing recovery in some cases. Particularly during the current economic depression the attention of the physician has been directed more and more to the psychological elements.

The chief difficulty that has stood in the way of the application of psychological methods to patients with peptic ulcers has been the belief that the psychological problems of these patients are strictly individual and require individual consideration, analysis and training. With the methods most commonly used, months and years are required to return the patient to a state of mental health. As a result of the individual approach, adequate psychological consideration has been effectively restricted to the wealthiest one or two per cent of the population. If each patient constitutes a brand new problem, essentially different in all important respects from every other, the individual approach would seem to be required. Under such circumstances there seems to be little probability that all peptic ulcer patients will ever be in a position to obtain satisfactory psychological attention.

There is some reason for believing, even in the absence of experimental evidence, that there is more commonness than individuality in the important psychological factors in peptic ulcer. There is, on the one hand, the marked commonness of primary and secondary symptoms: the digestive disturbances, the marked feelings of fatigue, the proneness to fear and anger responses and the decreased sexual activity. These are usually present. Constipation and increased susceptibility to pain also appear with notable frequency. On the other hand there is a marked commonness in the important psychological activities. It is usually found: (a) that the patients are worrying and dwelling on their difficulties almost endlessly; (b) that they talk about their disorders on any and all occasions with their friends, relatives and acquaintances, illness being their main topic of conversation; (c) that they are all trying to control one or another aspect of their condition through an "act of will" or "will power."

If these forms of behavior are regarded as the psychological activities which lead to the maintenance of peptic disturbance, one is faced with the problem of discovering the mechanism through which these activities come to influence the gastro-intestinal tract. In view of what is known of the physiological changes in emotion it seems unnecessary to invoke any hypothetical "conversion process." All that is required is to note: (a) that the emotional activity is associated with all of the ideas with which the patient concerns himself; (b) that the emotional activity is subject to modification by learning and (c) that these psychological activities constitute practice or learning mechanisms.

In emotion there appears to be hypermotility, spasm, flaccidity and a decreased blood supply in the gastro-intestinal tract. These might be expected to have some relation to gastro-intestinal health. In peptic ulcer satisfactory recovery necessitates the replacement of injured tissue with scar tissue. But the conversion of the materials of the body into scar tissue is a metabolic function. The body, or a part of it, cures itself when the conditions are favorable. The conditions favorable for recovery are rest of the diseased parts and an adequate blood supply. It is readily apparent that bodily rest and emotional hyperactivity are incompatible. The body cannot rest when the brain is in a state of agitation, for the brain cannot be active continuously in unpleasant emotional states without tending to stimulate efferent pathways. It would seem then, that if the emotional hyperactivity could be reduced, the conditions would result which would enable the body to cure itself more readily.

I. THE EXPERIMENTAL TECHNIQUE

In this experiment 52 patients were employed. All had the characteristic subjective signs and abnormal physiology as well as some of the objective signs of peptic ulcer. Those subjects who were examined and found to have no objective signs but only the abnormal physiology and subjective signs will be considered in another paper. This one will restrict itself to the 52 patients who appeared to be organic cases. All had

Respectively of *Columbia University, †Brooklyn Hospital and ‡Columbia University.
Submitted August 14, 1936.

been subject to peptic disturbance for a protracted period of time and had shown themselves to be resistant to satisfactory treatment through medication and diet alone. All had been diagnosed as peptic ulcer at least once before the diganosis was confirmed in the present experiment. All cases were ambulatory. No patient was accepted in whom the ulcerous condition was deemed to require surgical treatment. The attitude towards surgical treatment was that it was to be employed only if there was little probability of successful treatment with medication and the procedures outlined below. The attempt was made to recruit the patients from that seventy or so per cent of the peptic ulcer cases who "do not recover."

Diagnosis of peptic ulcer was made by means of the following procedures: 1. Complete medical history and physical examination; 2. Test meal for the determination of hydrochloric acid, total acid, mucus and food retention; 3. Stool examination where it was deemed advisable; 4. Fluoroscopy following a barium meal and 5. X-ray plates in doubtful cases.

The corroboration of the diagnosis of ulcer was made if the subject gave a typical ulcer history, showed hyperacidity and a niche or protrusion area in the stomach, in the case of stomach ulcer; or, in the case of duodenal ulcer, constant deformity of the cap in spite of relaxation with atropine to a point of disaccommodation, or a protrusion area or niche in the post pyloric region, or blood in the stomach or stool. All subjects were treated medically as private patients, but without change.

Following the diagnosis, all of the patients were put on a standard dietary and medical *regime*. The medication consisted of gastric mucin. Its supposed function was to neutralize hyperacidity and form a mucus coating on the mucous membrane wall and so plug up some of the gland ducts. The essential features of the diet were frequent feedings of moderate amounts of foods consisting of the high caloried lacto-farinaceous type and pureéd vegetables. In some cases some form of alkali was given in conjunction with the gastric mucin.

The subjects were then divided into two groups, an experimental group of thirty-two and a control group of twenty. The patients in the experimental group were then trained daily, seven days a week for a period of six weeks while nothing of a psychological nature was done for the control group. All differences between the experimental and control groups were in favor of the control group as may be seen from the following comparison:

	Experimental	*Control*
1. Age		
Range	26 - 63 years	27 - 59 years
Average	44 years	42 years
2. Period of some peptic disorder		
Range	2 - 30 years	2 - 25 years
Average	12 years	8 years
3. Period of recognized peptic ulcer		
Range	2 - 21 years	1 - 25 years
Average	8 years	7 years
4. Previous surgical treatment for peptic ulcer		
Number of cases	5	0
5. Number of previous reliable diagnoses of peptic ulcer		
Range	1 - 6 years	1 - 4 years
Average	2.6 years	1.6 years

II. THE TRAINING PROCEDURES

The experimental group was divided into two classes, each of which was in charge of one instructor. Since there were minor variations in the methods of the two instructors only a statement of the common features employed by the two will be given here. The primary difference was in the mode of explanation.

Six measures were employed in the attempt to induce the conditions desired in the patients. It is apparent that at least three corrective measures are necessary. A procedure for the control of each of the activities, worry, discussion and the use of "will power" are essential. Three others which give evidence of benefits were also employed.

1. *Control of worry:* While there are many and diverse ways through which worry may be eliminated, the procedures employed here are simple and direct. It is necessary that the patient learn to substitute some less unpleasant form of activity for the worry *behaviour. Such a substitution appears to be learned* with facility by most people in about three weeks, when they are properly directed and sufficiently well motivated; which is to say, when their illness makes them sufficiently uncomfortable.

The patients were instructed to pick out some period of their lives about which they had many pleasant, or not unpleasant, recollections. Each time they found themselves worrying, which was many times a day in the early stages, they were to direct their thoughts to the period of their lives that they had chosen and concern themselves as far as possible with the events of that period. For most people the recollection of childhood experiences serves well for this purpose. Any other period might be used equally well. Each time they found themselves worrying they were instructed to turn their attention to the recollections they had chosen and continue along that line until the thoughts were again back on their bothersome situations, when the attention was again to be turned to the chosen period. The patients had no great facility in diverting their thoughts for the first few days, but after three or four days they found it became easier. As with everything that is learned, facility in diverting the thoughts comes only with practice.

2. *Control of Discussion:* Despite the extent to which the patients discussed their difficulties with others, the control of discussion did not prove difficult. Once the patient learned that discussion of his difficulties was not in the interest of his eventual recovery he took immediate steps to eliminate it. To attain this end it was recommended that he seek the cooperation of the family as well as that of his close friends, who proved to be so weary of listening to his tales of woe that they were pleased to obtain the relief. Occasionally, wives and mothers required some persuasion. Before many days, any tendency on their part to remind the patient of his condition was met with anger on the part of the patient. This proved to be sufficiently persuasive to control even the most stubborn wife or mother.

3. *Control of Effort:* To eliminate effort it was necessary to show the subjects what they were doing to themselves through attempts to use their imaginary "will-power." The training here dealt with the specific situations in which they might be attempting to gain their ends through effort or a display of "mastery." For example, in attempting to divert attention from his worries the patient will commonly try to force his

thoughts along the new channels. The futility of this was demonstrated. He was then shown how to procede with a minimum of effort, since effort is in opposition to visceral rest. They were instructed not to make martyrs of themselves or fail to relieve emotional tensions because they felt that to do it was to "baby" themselves. They were to "baby" themselves on any occasion when they desired to do so. Many specific situations required consideration. The following is an example: One might have developed the habit of placing a glass of milk on the night table when he went to bed so he would have it handy when, and if, he should awaken with a pain in the epigastrium during the night. He may have felt that this was a bad habit and that he should take steps to break himself of it. While he would like to have the milk there, he felt that he was losing his "will" in these matters and he should assert himself against himself. This tendency to "assert himself" was an attempt to relieve the situation by effort. If he had the slightest inclination to take the milk to bed, he was instructed to do so whether he really needed it or not. He was more apt not to need it if it was there. The "habit" was insignificant, its development was unimportant. The important thing was that he should not go to bed with apprehensions of pain and absence of the remedial milk. In such cases, the patient was to be guided by his emotions, not by his ideas or those of some one else. Similarly with food when the diet was to be expanded. If there was some food of which he was afraid, he was to avoid it until he was largely rid of his fear, even though the physician may have told him that it was right for him to eat. When the time came that he wanted to try it, he was to take only a little of it, for only a little would give rise to only a little apprehension and the chances of success were relatively large. Once it had been successfully eaten he would be confident of the ability of his stomach to handle it and the apprehension would disappear largely or entirely.

Some procedures such as the above would be essential to satisfactory control of the emotional activity, but they do not exhaust the possibilities. Three others were employed.

4. *Explanation or Insight:* We tend to be most emotional about those adverse situations which we do not understand. Daily lectures for periods of forty-five minutes were devoted to the education of the patients with regard to the nature of thought and its influence on bodily activity, the patient's manner of reacting to the common situations in his life, the origin of his ideas and emotional reactions and many other factors bearing on the situation in hand. The value and efficacy of the medication and diet were frequently extolled. The procedures used were explained in detail and the manner of their operation illustrated whenever possible. Through these lectures the patient came to understand himself and the part he could play in maintaining his own health.

5. *Self-assurance or Self-suggestion:* Since each patient had built up an idea of himself as a very sick person whose eventual recovery was doubtful, it seemed desirable to have him build up a different conception of himself. The constant assurance to himself that he is recovering, by talking aloud to himself, offered an important possibility. For this purpose a phrase similar to that recommended by Coué was suggested for repetition while the patient was in bed in the evening and morning. While it would be difficult to say with certainty exactly what the mechanism is through which self-assurance achieves its effect there is one important factor that has sometimes been overlooked. Since emotional hyperactivity is only one aspect of a condition of which loss of confidence is another, everything must be done that can be done to build up the confidence of the patient, especially in himself. The self assurance and learning to divert his attention were things that the patient was doing for himself, through which he aided his own recovery. These things that the patient did for himself appeared to restore his confidence in himself to a marked degree and eventually to leave him independent of those who instructed him. In the light of the dependence frequently found in patients after education by some other psychological methods this may be significant.

6. *Assurance or induced suggestion:* The patients were given daily assurance of their ability to gain the ends they desired. This assurance covered digestion, absorption, sleep, vigor, elimination of emotional ideas and pains, correction of constipation and the development of confidence. This procedure goes back at least to Bernheim and is commonly called "induced suggestion." It appears to have marked value in producing feelings of well-being in the patient. No attempt was made to induce sleep in the patients while assuring them.

III. RESULTS

The patients in the experimental group were given thoroughly to understand that they were undertaking an experiment and that while there seemed good reason for believing that they might be benefited by the training, that this was the point which they were to determine. The attitude of the patient was that it was an experiment; that it was one more thing to try. None of them believed that it would do very much for him but since he had tried everything else without much gain he would follow instructions closely and give this a good try. About fifteen subjects dropped out of the experimental group because they did not believe there was a chance of their efforts repaying the expenditure of time, even though the lectures were given in the evening so as not to interfere with the working activities of the patients, and both the psychological training and the medical attention were gratis. These patients dropped out usually after the first or second lecture. The thirty-two who went through the six weeks gave the heartiest cooperation, regardless of what they themselves believed of one or another of our recommendations.

A. Immediate Results: After being trained for three weeks, at which time all of the subjects of the experimental group, with one exception, were free from subjective symptoms, the expansion of the diet was recommended. This was done in a given order for a week and then the patient directed his own expansion for the next two weeks. At the end of the six weeks' training period all but two of the thirty-two patients were eating about anything they wanted. Of these two, one expressed a preference for a slower expansion and required about two months to get back to a normal diet. The other showed no appreciable improvement throughout the experimental period nor subsequently. Both his peptic condition and his environmental situation were very severe. He was an elderly Italian, with a mild hemorrhage and who was

unemployed and about to lose his home on foreclosure and whose wife was about to have a baby.

The control group of twenty subjects remained on medication and diet for four weeks before the expansion of their diet was recommended. At this time all of the members of the control group were free from subjective symptoms. Within two weeks of the time that the expansion was started all but two had recurrence of symptoms. Of these two, one would not follow the recommendations for the dietary expansion, believing that it would certainly make him ill again.

A comparison of these results enables one unhesitatingly to draw the conclusion that the group procedures have a marked value in enabling peptic ulcer patients to rid themselves of their subjective symptoms and return to a satisfactory diet and mode of living.

B. Remote Results: It is frequently stated that peptic ulcers are never "cured." The fact that the patient may have a recurrence of his disorder is offered as evidence of this. On the basis of recurrence one might also say that pneumonia or a broken leg are never "cured." Under the proper conditions the patient may induce the same disorder again. If by "cure" one means that the patient in some way is put in such shape that he can never again have the condition, then one may certainly say that peptic ulcer is never cured. The fact that he has been able to develop the condition once is fair evidence that under the proper conditions the peptic ulcer patient can do it again.

A further question as to the value of the psychological training arises on this basis. Does the training aid the patients in maintaining in themselves those conditions which are in line with their continued health, and to what extent? To answer this question it is necessary only to permit a lapse of time. The interval of time between the end of the training period and the second examination varied from six to ten months, with an average of eight months. At the end of this interval complete tests for objective signs were again made.

Of the 31 patients in the experimental group who were well at the end of the training period, one had a recurrence at the end of three months which was as severe as his original condition. Four others were not examined. Three of these four reported that they were in excellent health but were unable to come for re-examination at the time requested. The fourth could not be located.

The remaining 26 were found to be in excellent health. Twelve of these reported one or more short periods of a return of the symptoms. The symptoms were reported to be mild and easily gotten rid of through return for a few days to the medical and psychological procedures recommended. The average duration of these recurrences was three days. The recurrences followed immediately after such events as an explosion of gas in the home, illness of a wife, death of a mother, breaking a finger, amputation of a toe, loss of a job, bankruptcy, and others of a simliar nature. All of these subjects, with the exception of the one whose recurrence was severe, reported themselves to be completely confident of their ability to take care of themselves if any symptoms did arise.

Since only two subjects in the control group survived the first part, our control group for this part of the expermient was not impressive. Both of these two control subjects had recurrences as severe as their original conditions within two months following the former seven weeks period.

Eight months is hardly sufficient time to follow peptic ulcer patients to determine how well they keep themselves. A final checkup was made at the end of three years. It is not planned to follow these subjects further. The following results were obtained at the end of the three year period.

Three of the experimental patients could not be located.

Ten have remained symptom free for the whole period. "Symptom free" is defined in this experiment as the state in which the patient has not had a return of symptoms for a day. Five others remained nearly symptom free. The average number of recurrences in these five were 1.8 per year. The average length of the recurrences were 4.9 days. The symptoms in all cases were reported to be mild and easily controlled. Each of these five considered himself to be in excellent health. The amount of disorder observed in these five is probably little, if any, more than will be found in the average of the population at large, which is to say that they are about normal.

Nine patients reported numerous recurrences of mild symptoms. Two reported single recurrence of hemorrhage from which they recovered quickly. The average length of recurrence for these eleven subjects was about six days. All but two considered themselves to be healthy and completely confident of their ability to handle successfully the symptoms which might arise, through recourse to the diet, medication and psychological measures.

Two others (including the one reported at the end of the eight month check-up) have had recurrences as severe as the original condition, from which they have not satisfactorily recovered.

From these remote results it is possible to conclude that not only is the group psychological training of value in amelioration of the symptoms in the first instance, but that it aids the patient in maintaining himself in a healthy condition for at least three years after the training. It seems possible to conclude, also, that the belief that emotional activity plays an important part in the maintenance of peptic ulcer is justified.

IV. REMARKS

From these results may be drawn a number of inferences which are important to psychology as well as to physiology. These will be considered in another publication. On the medical side there are some further observations that are worthy of note.

In cases of pyloric obstruction caused by scar tissue, a progressive obstruction is commonly observed. Several of the patients showed this type of obstruction with concommittant spastic phenomena. These have not, apparently, become any worse. Two cases were notable in this connection who had previously shown a marked retention at the end of six hours. After three years they showed some obstruction but the residual barium at six hours was slight. All of the cases who presented the symptoms of pyloric obstruction had vomiting before the experiment. In none of these had there been vomiting during the three years.

In about 20% of the cases the duodenal cap remained deformed although the patients were at the time free of subjective symptoms and in some cases

had been symptom free throughout the three years. The impression obtained from this is that the persistent deformity is caused by scarring in the first portion of the duodenum.

Perhaps the most significant medical finding is that in about 40% of the cases, at the end of the three year period what has commonly been considered as organic pathology could be observed without any subjective symptoms. This would seem to support the view that a diagnosis of ulcer should be made on the basis of how the patient feels as well as on his appearance before the fluoroscope.

The absence of subjective symptoms does not, however, exclude serious organic pathology. An elderly bookbinder, unable to work, volunteered for the experiment and was found to be in an advanced stage of carcinoma. His subjective symptoms were severe. Regularly each night he arose from bed five times for food to relieve his pains. Because of his circumstances it was deemed unwise to reveal to him his true condition. Rather, he was referred to the group with the expectation that he would attend until he lost interest and dropped out. To our great surprise he was free from his subjective symptoms at the end of seven weeks, was eating whatever he desired and returned to work at his trade. He remained free from his pains and died of carcinoma two months later. This case throws considerable light on the supposed cures of carcinoma through the agencies of magic, religion and other forms of psychotherapy.

Serum Lipase: Its Diagnostic Value

By

MANDRED W. COMFORT, M.D.*

ROCHESTER, MINNESOTA

ABOUT a year ago Osterberg and I (1) made a preliminary report on the value of determinations of serum lipase in the detection of pancreatic disease. We found that an increased activity of lipase in the serum was good evidence of disturbed pancreatic function, especially when such an increase was associated with signs and symptoms of cholecystitis, choledocholithiasis, cholangeitis, and pancreatitis. At this time I want to present additional data on the activity of lipase in the serum of normal persons and of patients with various diseases. While the report by no means answers all the questions that might be asked concerning the clinical application of the procedure, additional experience permits its presentation again as a satisfactory aid in the detection of pancreatic dysfunction.

METHOD

The degree of lipase activity of the serum was determined by the amount of olive oil hydrolyzed by a given quantity of serum in a given period of time. A modification of the Loevenhart method used by Cherry and Crandall (2), with a slightly different buffer solution, has been described previously.

VALUES FOR LIPASE IN THE SERUMS OF PATIENTS WITHOUT KNOWN ABDOMINAL DISEASE

The serums of two groups of persons without demonstrable organic abdominal disease have been examined for lipase activity. Group 1 contained 111 persons who did not have abdominal symptoms; group 2 contained seventy-two persons who had abdominal symptoms of a functional nature. The range is between 0.2 c.c. and 1.5 c.c. twentieth normal sodium hydroxide per 1 c.c. of serum. The most frequent values are 0.6, 0.7, 0.8, and 0.9 c.c. Comparatively few values were obtained that were less than 0.4 c.c. or more than 1.2 c.c.

The findings indicate that an olive oil splitting lipase is normally present in the serum of man. Such a finding is contrary to the experience of Crandall and Cherry (3) or of Jergesen and Simonds (4). Cherry and Crandall found that the serums of forty of forty-six patients did not reveal any trace of olive oil splitting lipase, and that the remaining six gave values of 0.3 c.c. or more. Jergesen and Simonds found that twenty-two of twenty-five persons had values for lipase of less than 0.3 c.c. In other words, these investigators found that the serum of man rarely contained an olive oil splitting lipase as is the case in dogs.

VALUES FOR SERUM LIPASE IN THE PRESENCE OF PANCREATITIS

With the development of acute pancreatitis, the values for serum lipase rise above the normal range and have reached 10.2 c.c. per 1 c.c. of serum. The curves in Figure 1 illustrate the behavior of values for serum lipase in cases of pancreatitis with and without disease of the biliary tract. It will be noticed that the rise is prompt, the values being high even on the day of the attack (Curves 1, 3, and 4), and that a fall in the value of lipase occurs within two or three days. The fall may be precipitous (Curves 1, 2, 3, and 4), and in some instances it may be followed by a secondary rise (Curves 1 and 4). In such cases, the clinical symptoms, including pain, fever, and leukocytosis, warrant the belief that the process remains active. In most cases normal values are obtained in the third week. In three cases slightly elevated values have been found later than three weeks after the attack, but again in these cases there is clinical evidence to indicate that the process has not been steadily resolving since the onset of the attack. In short, values for serum lipase following an attack of pancreatitis rise rapidly and they then fall rapidly or slowly to normal levels, which are usually reached within three weeks following the attack unless the pancreatitis

*Division of Medicine, The Mayo Clinic, Rochester, Minnesota.

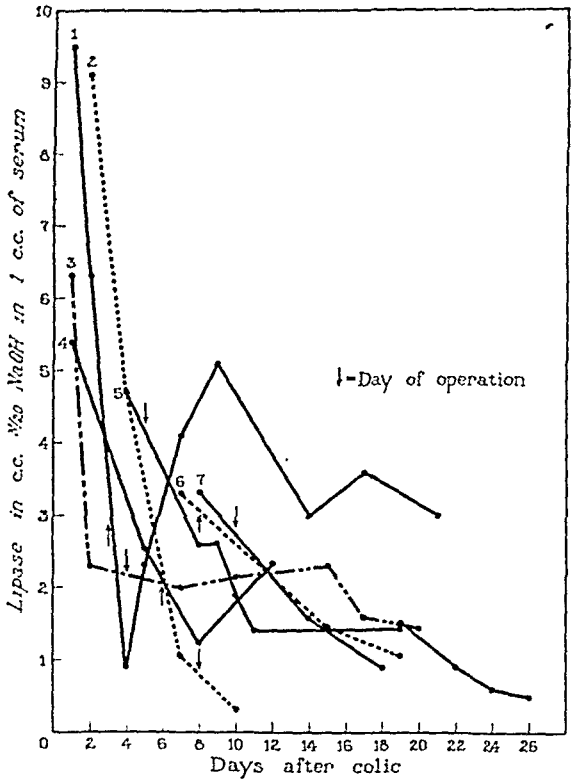

Fig. 1. Curves showing behavior of values for lipase in the serums of patients with acute pancreatitis.

fails to resolve. In a general way the more recent an attack, the higher the values for lipase.

Any explanation of the increase in the values for serum lipase must be theoretical. It may be presumed, however, that this increase is due either to absorption of secreted juice as a result of blockage of the ducts or to absorption of the enzyme from disintegrating pancreatic tissue. Crandall and Cherry (5) have suggested that pancreatic injury liberates a co-enzyme which activates normal blood lipase.

Studies on serum lipase had been carried out before operation in forty-five cases in which the surgeon reported pancreatic disease at operation. In the first twenty cases the clinical or pathologic data pointed to an acute process and the values were increased. In seventeen of the twenty cases in which the values were elevated the readings were obtained within ten days of the onset of the acute attack of upper abdominal disease or during a period of persisting symptoms. In the twenty-first case there was unimpeachable evidence of recent acute pancreatitis, yet the lipase values were normal. In this case, the process was acute and fulminating, and the patient died after ten days. At necropsy, the pancreas was completely necrotic. The rapid and complete disintegration of the pancreas, with destruction of lipase-producing tissue, may be advanced in explanation of the failure of the values for serum lipase to increase. In the remaining twenty-four cases the changes in the pancreas observed by the surgeon were slight and chronic or the determination of serum lipase was carried out fourteen to sixty days after the attack, a period of time sufficient for the lipase value to return to normal in spite of the apparent acuteness or subacuteness of the process in the pancreas. In these twenty-four cases the values were normal.

It is clear that elevated values are associated with acute and subacute pancreatitis, that such rises may fail to take place if pancreatic necrosis is extensive, that the values return to normal usually somewhere in the third week if not earlier, and finally that chronic pancreatitis does not cause elevation of values. So far I have been unable to find any evidence suggesting that in chronic pancreatitis the values for serum lipase are decreased below normal. In the few cases of extensive atrophy and calcification of the pancreas in which I have had the opportunity to determine the values for serum lipase, they have been within the normal range. The test appears to be quite accurate in the diagnosis of acute pancreatitis with or without associated disease of the gall bladder. In only one case out of twenty-one in which there has been clinical and pathologic evidence of the acuteness of the pancreatic process has elevation in the values for serum lipase failed to take place whenever the determination was made in the active phase of the disease.

VALUES FOR SERUM LIPASE IN MALIGNANT DISEASE OF THE PANCREAS

Increased lipase values have also been found in the serum in fifteen of forty-one cases in which malignant disease of the pancreas was present, the increases ranging as high as 6.4 c.c.

The behavior of serum lipase in cases of carcinoma of the pancreas involving the head of the gland and producing painless jaundice are graphically shown in Curves 3, 4, and 5, Fig. 2. In such cases the values for serum lipase tend to remain elevated, sometimes forming almost a flat curve, which persists after the relief of obstruction of the common duct by cholecystgastrostomy and suggests that obstruction of the pancreatic duct accounts for the elevation. In an occasional case (Curve 2, Fig. 2), in which the clinical picture undoubtedly justified a diagnosis of obstructive jaundice resulting from stone in the common duct and cholangeitis with pancreatitis, and in which the surgeon found a mass at the head of the pancreas so typical grossly of carcinoma that cholecystgastrostomy was performed, the rapid decline in the value for serum lipase resembles closely the behavior of serum lipase in the presence of acute pancreatitis. It is possible that superimposed pancreatitis may have markedly altered the behavior of serum lipase often seen in cases of carcinoma of the head of the pancreas. Further observations, together with the findings at necropsy, are needed to clear up this point.

Increased values for serum lipase also have been found in three of five cases of carcinoma of the ampulla of Vater. The behavior of serum lipase in these few cases is illustrated in Curves 1 and 6, Fig. 2. Curve 1 was constructed with the values obtained for serum lipase in a case in which the history of recurrent attacks of pain, with chills, fever, and jaundice, warranted a clinical diagnosis of cholecystitis with stones, obstructive jaundice attributable to stone in the common duct and cholangeitis. The surgical finding of apparent malignancy of the head of the pancreas was a complete surprise. Necropsy confirmed the presence of cholecystic disease and disclosed the malignant growth in the ampulla of Vater. Curve 1 differs

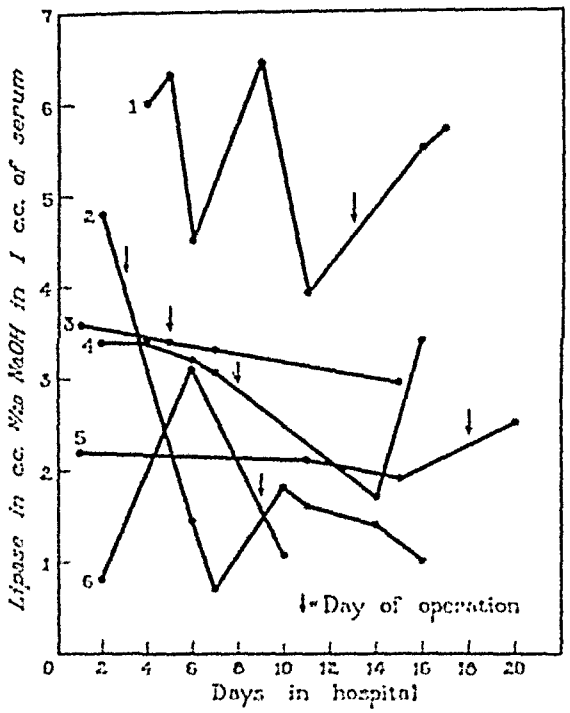

Fig. 2. Curves showing behavior of values for lipase in the serums of patients with carcinoma of the head of the pancreas or carcinoma of the ampulla of Vater.

from the curves seen in cases of carcinoma of the head of the pancreas by its irregular fluctuations, and from that seen in cases of pancreatitis by remaining at approximately the same average elevation for twenty-one days. The same rapid fluctuations in the values for serum lipase are seen in Curve 6, Fig. 2. The fluctuations are apparently related either to recurrent exacerbations of associated pancreatitis or to intermittent opening and closing of the ampulla of Vater.

VALUES FOR SERUM LIPASE IN DISEASES OF THE BILIARY TRACT

In Table I are listed 135 cases of disease of the biliary tract in which pancreatitis was not discovered at operation. In 116 of the 135 cases the values for serum lipase were normal; in the remainder they were elevated. Normal values occurred in all the various types of disease of the biliary tract. For this reason, some explanation other than disease of the biliary tract must be sought to explain the increased values in the nineteen cases. Crandall and Cherry have shown that an enzyme capable of splitting olive oil is present in appreciable amounts only in the tissues of the pancreas, liver, intestinal mucosa, and spleen. Disease of the spleen and of the intestinal mucosa does not occur in these cases. In view of Crandall and Cherry's work, the explanation must, therefore, be found in disease of the pancreas or liver.

It was not known that pancreatic disease was absent in any of the nineteen cases, for the condition of the pancreas was not described by the surgeon. In each of the nineteen cases the common duct was diseased. In seventeen of the nineteen cases the elevated values were obtained in the course of acute attacks of upper abdominal pain accompanied by symptoms and signs of inflammation, or within ten days of the onset of the attack, or in the course of exacerbations of jaundice accompanied by chills and fever. If the pathologic changes in the pancreas in these cases were known I believe the elevated values would be associated with pancreatitis or obstruction of the pancreatic duct by stone in the common duct.

Disease of the liver is a possible explanation in two of the five cases of stricture of the common duct. In these two cases there was extensive hepatic injury; however, as will be seen later, elevation of the value for serum lipase in hepatic disease is comparatively infrequent, and when present, theoretically at least, may be attributable to associated pancreatitis. Under the circumstances it seems that, associated with symptoms of disease of the biliary tract, elevated values for serum lipase in all probability indicate pancreatic dysfunction and, in the great majority of cases, dysfunction attributable especially to inflammation of the pancreas.

VALUES FOR SERUM LIPASE IN DUODENAL ULCER

Elevated or increased values for serum lipase occurred in five, or 7 per cent, of the seventy-one cases of duodenal ulcer (Table I). The occurrence of elevated values for serum lipase in the five cases of duodenal ulcer is not surprising considering the close proximity of the duodenum to the pancreas. This increase, however, seems to be much less than that found by Jergesen and Simonds, using 0.2 c.c. twentieth normal sodium hydroxide as the upper limit of normal. They found that thirty-eight (76 per cent) of fifty cases had increased values for lipase in the serum.

The involvement of the pancreas by the process in the duodenum seems to be the explanation for the increased values, at least it was so in three of the five cases in which the values were elevated. In these three cases the surgeon found that a subacute duodenal ulcer had perforated to the pancreas and formed a mass in the first case; that an acute duodenal ulcer had perforated to the gall bladder, producing acute cholecystitis, and to the pancreas, forming a mass of considerable size, in the second case; and that an acute duodenal ulcer, associated with acute purulent cholangeitis, was present in the third case. Of the two remaining cases, in one, operation was not performed, and in the other the surgeon merely described the chronic duodenal ulcer and did not mention the pancreas.

VALUES FOR SERUM LIPASE IN HEPATIC DISEASE

Elevated values occurred in five, or 13 per cent, of thirty-seven cases of hepatic disease (Table I). The diagnoses in these five cases were: hepatitis with jaundice due to Malta fever, hepatitis with jaundice due to lobar pneumonia, toxic hepatitis due to cinchophen poisoning, toxic cirrhosis of unknown etiology, and biliary cirrhosis. Elevation of the value for serum lipase in hepatic disease seems to be the exception rather than the rule, contrary to the experience of Cherry and Crandall.

Crandall and Cherry suggested that the lipase may be absorbed from the injured liver or that the injured liver fails to remove the lipase, which naturally passes into the blood from the gastro-intestinal tract whereas the normal liver acts as a barrier to this substance.

Consideration must be given to other explanations for the increased values in hepatic disease, for many other cases of hepatic disease, with much more destruction of hepatic parenchyma than was found in these five cases, were not associated with increased values for serum lipase. In the cases of Malta fever and lobar pneumonia, it seemed just as logical to explain the elevated values for serum lipase on the basis of a secondary pancreatitis as it was to explain the jaundice on the basis of an associated hepatitis. It is even possible that the toxic or infectious agent producing the hepatitis in the remaining three cases likewise produced a disturbance of pancreatic function. Whichever explanation for the increased values in hepatic disease is correct, certainly from a clinical standpoint these occasional elevations are not very important. In the case of Malta fever and pneumonia, the elevations were not of diagnostic interest. In the other three cases, the elevations were so slight and inconstant that one's clinical judgment could hardly have been influenced by the findings.

TABLE I

Values for serum lipase of patients with disease of biliary tract, duodenal ulcer and hepatic and various other diseases

	Cases in which lipase was more or less than 1.5 c.c. of N/20 NaOH per 1 c.c. of serum		
	Less than 1.5 c.c.	More than 1.5 c.c.	Total Cases

Uterine cervix	1	0	1
Total	48	1	49
Miscellaneous diseases	82	3	85

VALUES FOR SERUM LIPASE IN MALIGNANT DISEASES

Normal values for serum lipase were obtained in forty-eight cases of carcinoma of the stomach and large intestine, abdominal carcinomatosis, and carcinoma of the breast, urinary tract, and uterine cervix (Table I). In one case of carcinoma of the stomach there was a slight elevation of the value for serum lipase. In this case, carcinoma of the stomach had perforated to the pancreas. The involvement of the pancreas probably explains this exception to the general rule that malignant processes other than in the pancreas itself are not associated with elevations of the serum lipase.

VALUES FOR SERUM LIPASE IN VARIOUS OTHER DISEASES

Under the heading "miscellaneous diseases" in Table I are grouped eighty-five cases. Included were patients with indeterminate gastric complaints, questionable cholecystitis, and syndromes following cholecystectomy; patients who had previously undergone cholecystectomy, with or without pancreatitis at the time of operation; patients who were pregnant; and patients with healed duodenal ulcer, gastric ulcer, hypertrophic gastritis, gastrojejunal ulcer, primary duodenal obstruction, congenital cystic liver, residual hepatic dysfunction, sprue, diabetes mellitus, hyperinsulinism, partial intestinal obstruction, acute appendicitis, acute intestinal obstruction, Addison's disease, Hodgkin's disease, abdominal abscess, pulmonary abscess, puerperal septicemia, peritonitis of undetermined etiology, hyperthyroidism, myxedema, and pernicious anemia. In eighty-two of these cases the values for serum lipase were normal. In only the remaining three cases were the values elevated. The first was a case of peritonitis of indeterminate etiology, the second a case of puerperal septicemia, and the third a case of pulmonary abscess. In these three cases, in this stage of the study of lipase, the elevated values for serum lipase are probably best explained on the basis of pancreatitis secondary to an infectious process.

Crandall and Cherry reported that in twelve of nineteen cases of multiple sclerosis, the values for serum lipase were increased above the limit accepted by them as normal. This series does not contain cases of that disease.

SUMMARY AND CONCLUSIONS

A simple titration method for the determination of values for serum lipase, using olive oil as a substrate, has been applied clinically to normal persons and to patients with a wide variety of diseases.

The upper limit of the values for lipase in the serums of persons without pancreatic disease appears to be about 1.5 c.c. of twentieth normal sodium hydroxide.

Elevated values for serum lipase have been found in 95 per cent of the cases of acute pancreatitis, in 36.5 per cent of those of carcinoma of the pancreas, and in 60 per cent of those of carcinoma of the ampulla of

Vater. An increased activity of the serum lipase appears to be a very efficient test for pancreatitis, less so for malignant disease of the pancreas. The increased values in these diseases followed inflammation of the gland or obstruction of the pancreatic duct by carcinoma. Elevated values appear in cases of acute inflammation of the pancreas immediately after the onset of the attack, and as a rule they decline to normal levels within three weeks or even earlier in the course of the disease. It would appear that elevated values occur in acute inflammations of the pancreas so long as an adequate amount of lipase-producing tissue is present, and less frequently in malignant disease, depending on the presence or absence of obstruction of the pancreatic ducts or on the presence of inflammation associated with a malignant process in the pancreas.

An elevated value for serum lipase does not of itself distinguish between inflammation and malignancy of the pancreas. The interpretation of the increase in lipase activity of the serum must depend on the associated clinical findings. If the symptoms point to inflammation of the biliary tract, the elevated values for serum lipase will usually indicate an associated pancreatitis or obstruction of the pancreatic duct by a stone impacted in the ampulla. If the symptoms point more to inflammation of the pancreas than to inflammation of the biliary tract, elevated values for serum lipase should be confirmatory evidence of the clinical suspicion of pancreatitis. In the presence of a painless jaundice, elevated values for serum lipase will usually point to the presence of carcinoma of the head of the pancreas.

The behavior of the values for serum lipase seems to be somewhat distinctive of the type of pathologic condition present. If these values rise rapidly following an acute attack of upper abdominal pain, and then fall gradually or rapidly to normal levels, such behavior favors the presence of pancreatitis. If the values for serum lipase in the presence of a painless jaundice are increased and sustained at a fairly constant level, carcinoma of the head of the pancreas is probably present. If the values for serum lipase are elevated but fluctuating, carcinoma of the ampulla of Vater must be suspected. An acute pancreatitis associated with malignant disease of the pancreas may alter the type of curve and obscure the diagnosis.

Values for serum lipase were elevated in 7 per cent of the cases of duodenal ulcer. Such elevations in this disease probably point to an acute perforation of the ulcer to the head of the pancreas, or point to an associated inflammation of the common duct with pancreatitis.

Disease of the liver was associated with elevated values for serum lipase in 13 per cent of the cases. The elevation is apparently due either to destruction of the hepatic parenchyma or to the presence of an associated pancreatitis. Clinically, up to the present time, these elevations have not proved confusing, and as a rule they have been so slight and inconstant that clinical judgment was not influenced.

The determination of serum lipase activity promises to be a very valuable procedure in the laboratory diagnosis of acute pancreatitis and of pancreatic malignancy, especially when correlated with the clinical symptoms. So far it has proved of greater value in the diagnosis of acute or subacute inflammation of the pancreas than any other procedure we have used.

Prophylactic Treatment of Peptic Ulcers Produced Experimentally by Cinchophen*

By
LEONARD K. STALKER, M.D.†
JESSE L. BOLLMAN, M.D.
and
FRANK C. MANN, M.D.‡
ROCHESTER, MINNESOTA

PREVIOUS studies by Van Wagoner and Churchill and by us have shown that the administration of cinchophen is an effective method for the production of chronic peptic ulcers in dogs. In a series reported by us peptic ulcer developed in approximately 96 per cent of the animals following oral administration of the drug (3). A few of the ulcers were duodenal but the majority were gastric. The use of bone as a mechanical irritant increased the rapidity of the formation of the ulcers. The ulcers occurred after absorption of the drug and began with an initial destruction of the mucosal cells. Progression and healing were similar to that observed in other experimental studies of peptic ulcer and to that observed in cases of ulcer in man.

It was then thought advisable to apply some of the surgical and medical methods used in the treatment of peptic ulcer in man to the treatment of dogs with peptic ulcers which had been produced by the administration of cinchophen. But since chronic ulcers heal rapidly when the administration of cinchophen is discontinued, and complete healing has been noted as early as two weeks and as late as seven weeks thereafter, the healing process was too rapid to enable us to evaluate with any degree of certainty the effectiveness of any form of prophylactic treatment. It was then decided to determine the effect of prophylactic treatment of peptic ulcer while the animals were being given cinchophen.

The following medical agents seemed to be in most general use in the treatment of peptic ulcer in man and were therefore employed: (1) A diet of milk alone, (2) alkaline powders plus a milk diet, (3) mucin, (4) duodenal extract, and (5) histidine monohydrochloride. A bland diet was used in all cases. Since gastro-enterostomy is one of the most universally used surgical treatments for peptic ulcer, it was selected. In addition pyloric exclusion or partial gastric exclusion was performed in a number of cases primarily to determine whether or not a peptic ulcer produced by administration of cinchophen could be produced in the absence of free hydrochloric acid.

METHOD OF INVESTIGATION

Forty-five dogs with a range of average weight varying from 11 to 32 kg. were used in these studies. In every case the dogs were normal before the experiment began. All normal dogs can be considered not to have peptic ulcers as statistics have shown this to be true. The dogs were given the routine kennel care and the majority were fed a diet composed of cracker crumbs, ground horsemeat, and evaporated, skimmed milk. This diet was of a calculated weighed amount known to be sufficient to meet the caloric requirements of the dog. A capsule containing 2 gm. of cinchophen, unless otherwise mentioned, was given to each animal daily for the first four days of each week. On the last three days no cinchophen was given, but the usual diet and prophylactic treatment were continued.

Several animals were used in preliminary studies for standardization of the methods of treatment employed. These were not included in this report.

All surgical procedures were performed while the animals were under surgical narcosis induced by ether, and a careful aseptic technic was employed. All dogs killed were given a light ether anesthesia and were then bled from the femoral arteries. These and the dogs that died were examined completely. Careful gross and microscopic examination was made of all demonstrable lesions.

RESULTS OF MEDICAL TREATMENT

Milk therapy. Two dogs, averaging 14 kg. in weight, were given a diet composed wholly of evaporated skimmed milk with a small amount of corn syrup added for sweetening. Three feedings of an amount exceeding that which the dog would take were given daily. In this way some milk was constantly present for the dog to take. If the animal refused the milk it was given by stomach tube. Cinchophen was administered as mentioned before and the milk was given for thirty consecutive days.

The nutrition of these two animals remained excellent during this period. One dog gained 1 kg.; the other lost 1 kg. They were killed on the thirty-first day. In each case a gastric ulcer, which appeared much less severe both grossly and microscopically than

*From the Mayo Clinic, Rochester, Minnesota.

Submitted October 27, 1936.

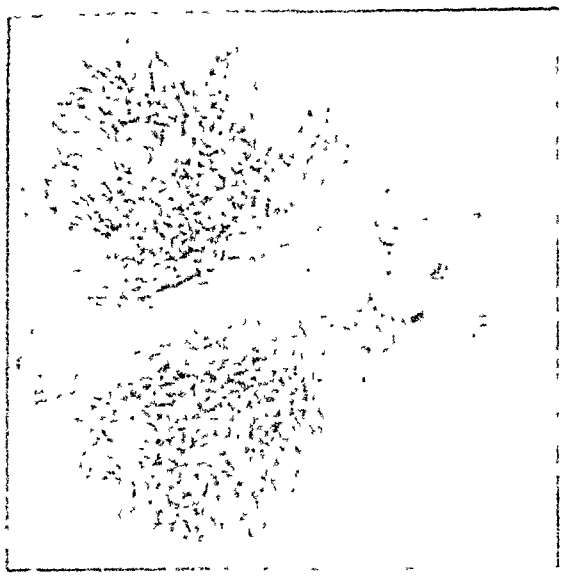

Fig. 1. Subacute ulcer on posterior wall of pylorus with surrounding mucosal erosions, gastritis, and a healed gastric ulcer on the posterior wall high in the pyloric antrum. This dog was treated with a diet of milk alone.

any of those seen in the control group (dogs given cinchophen but no prophylactic treatment) was found at necropsy. In one animal there was a completely healed gastric ulcer located on the lesser curvature and posterior wall of the stomach very near the pyloric ring. Just above this on the posterior wall, and also on the anterior wall directly opposite, was a small acute ulcer which involved the submucosa. In the other animal there was a small, subacute perforating pyloric ulcer located on the posterior wall. In addition, there were a few surrounding mucosal erosions, a slight degree of gastritis, and a completely healed ulcer high on the posterior wall of the pylorus (Fig. 1).

In comparison with the control animals, the animals receiving milk gave evidence of much less reaction from the cinchophen. The only clinical evidences that an ulcer was present were a few tarry diarrheal stools and vomiting. The gastritis, although to a lesser degree however appeared as soon in these cases, but the process seen at necropsy was definitely acute to subacute in contrast to the chronic process seen in animals which had received a more irritating diet. The ulcers were much smaller and gave more evidence of healing than is usually seen.

Alkaline powders plus milk diet. Five dogs averaging approximately 15 kg. in weight were given a modified Sippy treatment. An alkaline powder of bismuth subcarbonate (10 grains; 0.65 gm.) and magnesium oxide (4 grains; 0.24 gm.) was given at 8:00 and 11:30 a. m. and at 3:30 p. m. A powder of calcium carbonate (8 grains; 0.5 gm.) and sodium bicarbonate (6 grains; 0.4 gm.) was given at 10:00 a. m. and at 2:00 and 5:00 p. m. The 2 gm. capsule of cinchophen was given at 8:00 a. m. A pan of milk and syrup in excess of the amount desired was given at 9:00 a. m., 12:00 m. and 3:00 p. m.; in addition, a large pan of milk and syrup was left in the cage for the dog to take during the night if he so desired. The powders and milk were given daily. In none of these five cases did a chronic lesion develop although a chronic lesion did develop in every animal in the control group. Each of these five animals had the usual gastritis during the first two weeks, but in the majority this had entirely disappeared by the thirtieth day.

At necropsy, an entirely normal appearing stomach was found in two cases. In a third animal there was a small (2 mm.) mucosal erosion near the pyloric ring and on the lesser curvature (Fig. 2). In addition, there was a nearly healed erosion on the greater curvature. In the fourth animal a rather mild diffuse gastritis was present, with a few minute erosion but no actual ulcerations. The fifth dog had a relatively normal stomach, but a small, superficial, healing mucosal erosion was present on the posterior gastric wall. The nutritional status of these animals at the time of necropsy was excellent. Each animal had lost on an average of about 1 kg.

The clinical picture of gastritis, that is, the tarry stools and occasional vomiting, as has been said, developed as soon but to a less degree in the treated animals as in the untreated (control) animals. In no case were we able to produce much more than gastritis in any of the treated dogs. In no case did a sizeable acute ulcer develop and in none was a chronic lesion seen. The animals tolerated the alkaline therapy well.

Gastric mucin. Four dogs of an average weight of 21 kg. were given 12 to 15 gm. of gastric mucin mixed in milk at 8:00 and 11:00 a. m. and at 2:00 and 5:00 p. m. daily. Two grams of cinchophen was administered at 8:00 a. m. The regular diet in which an additional 15 gm. of mucin had been mixed was given at 9:00 a. m.

In two cases the stomach appeared entirely normal at necropsy. In the third case there was a large, chronic, perforated gastric ulcer on the posterior wall very near the pyloric ring. Perforation was through the gastrohepatic omentum with penetration into the substance of the liver. In the fourth animal a large chronic ulcer was found at necropsy on the posterior

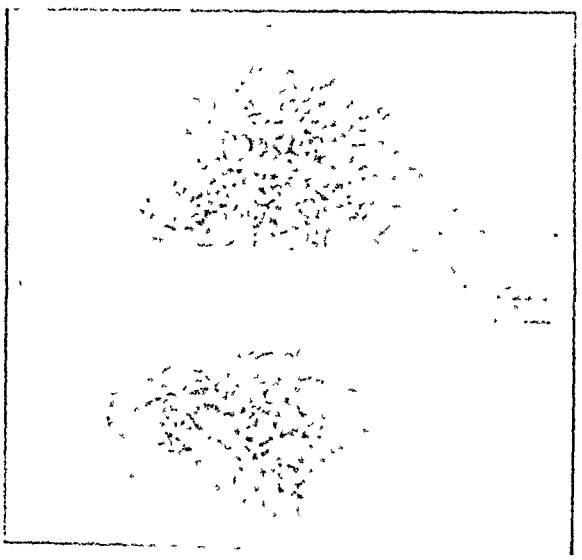

Fig. 2. Small mucosal erosion of the lesser curvature and nearly healed erosion of the greater curvature of the stomach of a dog treated with alkaline powders and a milk diet.

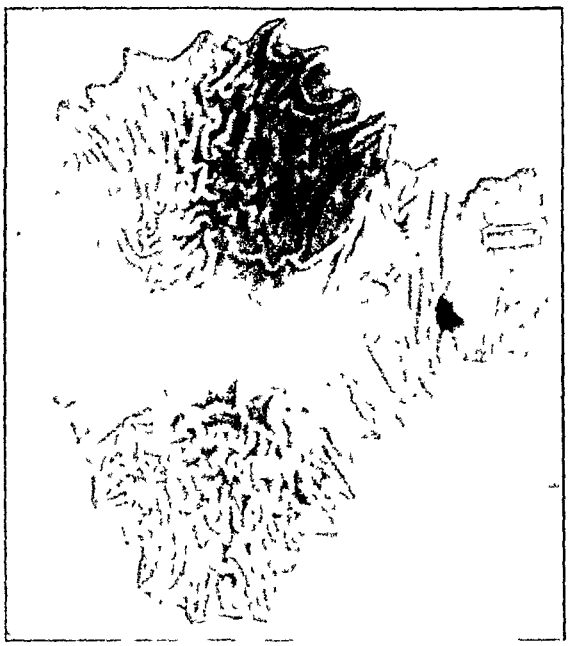

Fig. 3. Chronic ulcer on the posterior wall and lesser curvature of the stomach of a dog treated with gastric mucin.

wall of the lesser curvature near the pyloric ring (Fig. 3).

The symptoms of gastritis such as were seen in the control group developed in each animal receiving mucin. There was more diarrhea in this group, but grossly the amount of blood in the stool was much less. The animals' appetites were good for a longer period of time and there was less vomiting when mucin was given In no case was there any alteration in the nutritional state, and in general the animals given mucin were in a better state of nutrition than some of those in the other groups. Two of the dogs gained 2 kg ; the weights of the other two remained the same. The symptoms of peptic ulcer in the two animals in this group in which ulcer developed were less severe than in the control group.

These animals seemed to enjoy taking mucin and in most cases took it voluntarily. On a few occasions, however, it was necessary to administer it by means of stomach tube The two ulcers which developed were as severe as any in the control group, but in contrast there was no microscopic or gross evidence of damage to the stomachs of the other two animals in which lesions did not develop.

Histidine monohydrochloride. Four dogs were given a daily intramuscular injection of 5 c.c. of a 4 per cent solution of histidine monohydrochloride in addition to the bland diet previously mentioned. Two grams of cinchophen was administered four days of each week.

In none of these cases was any benefit observed as a result of the injections of histidine. A large, chronic peptic ulcer which was grossly and microscopically as severe as any seen in the control group developed in each of the four dogs (Fig. 4). Gastritis with clinical symptoms developed as early in these dogs and the symptoms of ulceration were as severe as in the control group. Their nutritional state was relatively unaltered, although three animals lost more than 1 kg. in weight. In every case the chronic ulcers were located in the pyloric region of the stomach on the lesser curvature and posterior wall. In one case the ulcer had perforated and there was an associated general peritonitis. No local or systemic reactions were noted from the injection of histidine.

We were unable to detect any alteration in the course of the development of the ulcer produced by cinchophen following injections of histidine.

Duodenal extract (2). Four dogs of an average weight of 21 kg. were given 150 grains (10 gm.) of duodenal extract daily. This was divided into three doses of 50 grains each and was given in capsules at 8:00 a. m., 12:00 m. and 4:00 p. m. Two grams of cinchophen were given at 8:30 a. m. for four days and the usual diet was given daily.

In every one of these cases there was some demonstrable lesion of the gastric mucosa, but in no case were these lesions as severe as those seen in the control group. No stomach was considered to be entirely negative, but one revealed only a rather mild diffuse gastritis with multiple small linear erosions. In the stomach of a second animal there were multiple, small acute ulcers, and a subacute ulcer about 1 cm. in diameter on the lesser curvature and posterior wall of the stomach near the pyloric ring (Fig. 5). The other two animals showed a rather diffuse gastritis with multiple mucosal erosions and small acute ulcers. In one of these there was a completely healed ulcer on the lesser curvature, and in the other there was much evidence of healing but no completely healed lesion. At necropsy an increased amount of mucus was found in the stomach of each of these four animals. The clinical symptoms of gastritis and ulceration appeared as early in this group as in the control group but were generally much less severe. The nutritional state of these four animals remained unaltered throughout the experiment.

These dogs were all somewhat larger than those used in the other groups, but chronic lesions developed

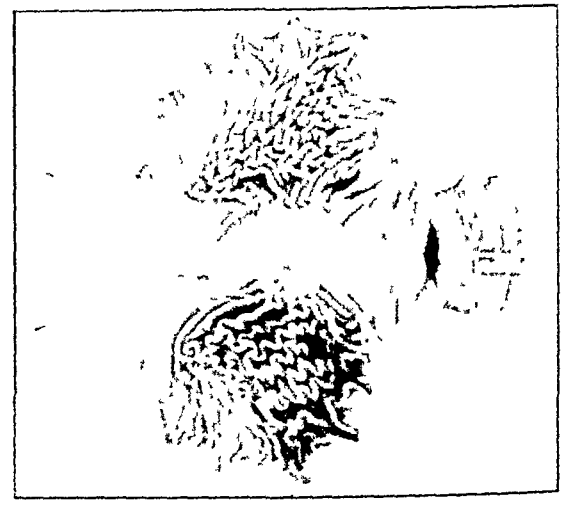

Fig. 4. Chronic ulcer on posterior wall and lesser curvature of stomach of a dog treated with histidine monohydrochloride. A similar type of ulceration was seen in the control animals.

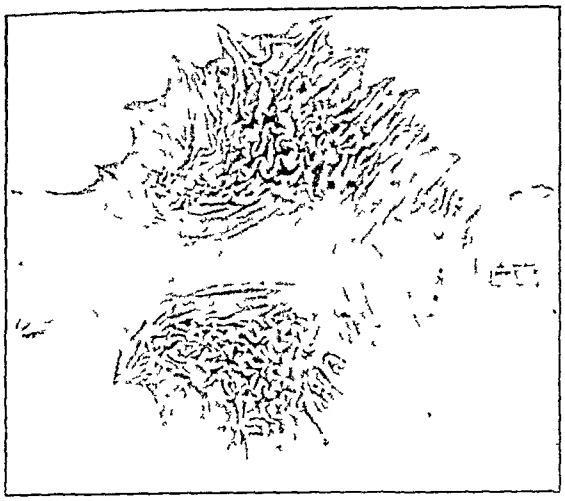

Fig. 5 Multiple acute and subacute ulcers in the stomach of a dog treated with duodenal extract.

in all animals of similar weight in the control group. The increase in mucus in these animals' stomachs seemed to be quite definite, although no actual measurement was made Frequently the appearance of the stomach at necropsy suggested that the animal had recently ingested a large amount of mucin. The toxic picture was about the same in these animals as in those receiving mucin; it was more severe than in those receiving the alkaline powders and milk diet, but was less severe than that presented by animals in the control group. It would seem possible that the action of the duodenal extract in these animals might have been brought about by an increase in the mucus secretion of the stomach, which in turn acted as a demulcent and prevented much of the acid erosion of the damaged mucosa.

CONTROL GROUP

Five dogs whose weight varied from 11 kg. to 31 kg. were used as controls. These were fed daily the usual diet of ground horse-meat, cracker meal, and evaporated milk and were given 2 gm of cinchophen four days of each week.

Two of the dogs died before the thirtieth day as a result of peritonitis from perforated gastric ulcer. The remaining three were killed on the thirty-first day. In one there was a chronic perforated ulcer on the lesser curvature, 1 5 cm. in diameter and approximately 2 cm. from the pyloric ring; in addition there were several contact ulcers, a large posterior wall ulcer in the cardia, and a diffuse mild gastritis with multiple erosions. A similarly severe picture was found at necropsy in the remaining two cases, a large, chronic gastric ulcer located on the lesser curvature and posterior wall near the pyloric ring being present in each.

Gastritis developed as usual from approximately the fifth to the twelfth day. The clinical symptoms were more severe in this group than in any treated group with the exception of those animals receiving injections of histidine, and no noticeable difference was noted between these two groups. In both these groups there was more vomiting, more pronounced tarry diarrhea, a greater degree of anemia and anorexia, and in general the animals appeared and acted sicker than in any of the other groups. In no case, however, was the nutritional state markedly altered, because the majority of the animals maintained their original weight.

RESULTS OF GASTROJEJUNOSTOMY

Anterior gastrojejunostomy was performed on five dogs whose average weight was 18 kg. This was done by anastomosing the jejunum to the greater curvature of the stomach with two and three rows of chromic catgut. Clamps were not used. The stoma was made about three times the diameter of the jejunum. The animals were allowed three to four weeks in which to recover from the operation and in every case were apparently in normal condition and had a perfectly functioning anastomosis before any experimental procedures were carried out. The usual diet was given daily in addition to 2 gm. of cinchophen, which was given on only four days of each week.

In each case the clinical symptoms of gastritis developed, but in no case was a gastric ulcer or gastrojejunal ulcer found at the time of necropsy. These symptoms of gastritis were usually as severe as in the control group, but at no time did they become as severe as those so frequently seen when an ulcer is present. The most outstanding symptom was anorexia, which developed about the fifteenth day. In these cases it was necessary to force feed in the animals. If this was done, food was usually retained and at the time of necropsy there was very little change in the nutritional state of the animals.

Two of the five dogs died as a result of pulmonary infection after the twentieth day of cinchophen administration; in each of these animals there was a mild gastritis with a few linear erosions, but no ulcer. The stomach, jejunum, and duodenum of two of the dogs that were killed on the thirty-first day appeared to be entirely normal. The jejunum and duodenum of

Fig. 6. Gastritis but no ulcer and a negative jejunum and duodenum in a dog on which gastrojejunostomy had been performed.

Fig. 7. Perforated chronic ulcer with multiple acute to subacute jejunal ulcers in the stomach of a dog subjected to pyloric exclusion. The excluded segment of a stomach to the right is negative, the dark discoloration being due to bile.

the fifth animal were negative, but marked gastritis with multiple mucosal erosions was present throughout the acid-secreting portion of the stomach (Fig. 6). The pyloric mucosa was entirely free from injury.

Posterior gastrojejunostomy is most frequently performed in man, but because of the ease of performance and a slight variation in anatomy, anterior gastro-enterostomy is usually performed in the dog. We feel that anterior gastro-enterostomy in the dog is equivalent to posterior gastro-enterostomy in man. At no time has it been necessary to perform entero-anastomosis. On a few occasions, in other experiments, a reversal of the afferent and efferent loops was done, but no differences could be noted.

THE ACID FACTOR IN THE PRODUCTION OF THE PEPTIC ULCER

We have previously shown that when an isolated pouch is made from the fundic portion of the stomach, a perforating peptic ulcer develops in the pouch when cinchophen is administered orally (3, 4). These ulcers form with greater rapidity than ulcers in the stomach proper. In the majority of such cases the ulcer perforated the wall of the pouch and peritonitis developed before there was much noticeable damage to the stomach proper. This was attributable to the fact that there was constantly some free hydrochloric acid present in the pouch. In addition, there was no alkalinizing mechanism, such as duodenal regurgitation, and emptying of the pouch was never complete.

The secretion of the pyloric portion of the stomach is slightly alkaline in contrast to the secretion of the rest of the stomach which is acid. More than 90 per cent of chronic ulcers produced by the administration of cinchophen are located in the pyloric region. It occurred to us that it might be possible to exclude this pyloric portion of the stomach and then administer cinchophen in an attempt to produce a peptic ulcer in the excluded segment. If no ulcer developed in this segment, a greater portion of the stomach, including part of the acid-secreting mucosa, could then be excluded in the same fashion. Cinchophen could then be administered to these dogs and, if an ulcer developed in the excluded portion of stomach, it might be said that the presence of free hydrochloric acid was essential for the development of peptic ulcers produced by cinchophen.

Anterior gastrojejunostomy was accordingly performed on sixteen dogs which varied in weight from 7 to 23 kg. This was done with the same technic as before, with the exception that the stoma in most cases was placed well above the pyloric portion of the stomach, and in a few cases was placed at the cardiac end of the stomach. The dog was allowed to recover completely from this operation and, when it appeared normal and had been eating its regular diet without distress for some time, a second operation was done. Exclusion of the entire pyloric portion of the stomach of eleven of the animals was then performed. This was done similar to the method of Devine (1925). In the remaining five animals approximately half of the entire stomach was excluded in a similar manner.

After three or more weeks in which to recover each of these animals was then given a daily dose of cinchophen and the usual diet.

The eleven dogs in which only the pyloric region had been excluded were given cinchophen in total amounts varying from 10 to 118 gm. over a period varying from five to 114 days. The average period was forty days, with the average total dose being 61 gm. of cinchophen.

There was no gross or microscopic evidence of injury to the excluded pyloric segment of the stomach of these eleven dogs. In four instances a jejunal ulcer was located on the posterior wall of the efferent loop of jejunum, near the gastro-enteric stoma, and in one of these cases the jejunal ulcer had perforated and the dog had died from generalized peritonitis (Fig. 7). The other seven dogs showed no evidence of jejunal ulcer. In ten of the animals there was definite gross and microscopic evidence of gastritis and small mucosal erosions diffusely scattered throughout the stomach. The eleventh animal in this group showed no damage to the gastric mucosa. In no case was a definite gastric ulcer present.

Fig. 8. Two acute ulcers and gastritis in the excluded segment of stomach.

In every case these eleven animals manifested symptoms of gastritis in the usual period of time. At necropsy this gastritis varied from a mild to a rather severe degree, but in the majority of instances the gastric mucosa was slightly edematous, with multiple linear erosions containing small blood clots and, in a few cases, small mucosal ulcerations.

The five animals in which nearly half the stomach had been excluded were given cinchophen in doses varying from 1 to 2 gm. daily for a period varying from six to forty-eight days, an average total period of twenty-three days elapsing and 25 gm. of the drug being the average total dose. Jejunal ulcer developed in three of these animals. These ulcers were in the same location as the jejunal ulcers in the previous group. In two instances the jejunal ulcer had perforated and the animals died from general peritonitis. The remaining two animals which did not have jejunal ulcers, died as a result of toxemia.

In all five instances there was gastritis similar to that described, but, in addition, the major process was in the excluded segment of the stomach. In one animal there was a definite gastritis in this excluded segment with two acute ulcers, 1 cm. in diameter, on the posterior wall in the pyloric mucosa close to its junction with the acid-secreting mucosa (Fig. 8). In another animal there was a large amount of bloody material in the duodenal loop, with diffuse gastritis of the excluded stomach. There were multiple erosions and small ulcerations throughout this entire segment. The excluded portion of the stomach of a third animal was filled with blood clots. There was diffuse gastritis of the entire mucosa with several small acute ulcers in both the pyloric and fundic mucosa of this segment. In contrast, the stomach proper showed only a mild gastritis. No jejunal ulcer was present. The other two animals' stomachs demonstrated similar pictures, and in both cases there was marked gastritis with an associated acute ulcerative condition in the excluded segment.

In the majority of these cases in which some surgical procedure was carried out gastritis developed within the expected period of time. In no case, however, was a true peptic ulcer produced in the stomach or duodenum following any of these procedures. In seven of the sixteen animals (43.7 per cent) in which an exclusion operation was performed a jejunal ulcer developed, but a jejunal lesion did not develop in any of the animals in which only gastrojejunostomy had been performed.

The symptoms presented by the animals when a jejunal ulcer developed were the same, but to a more severe degree, as those present when a gastro-duodenal ulcer develops. The fact that in all of the animals in which some of the acid-secreting mucosa was excluded, definite ulcerative damage of the excluded mucosa developed would suggest that free hydrochloric acid is essential for the development of peptic ulcers produced by cinchophen. The ulcers which did develop in the excluded segment of the stomach were always acute to subacute and were much less severe than those that developed in unaltered stomachs. This may be due to the lesser degree of mechanical irritation to the isolated portion of the stomach.

SUMMARY AND CONCLUSIONS

Some benefit was found from a diet of milk alone and from the use of a duodenal extract in the prophylactic treatment of peptic ulcers produced experimentally by the administration of cinchophen. Mucin appeared to be definitely beneficial in some cases but in others a chronic ulcer developed similar to those found in control animals fed cinchophen without prophylactic treatment. A chronic lesion was not produced in the presence of alkali-milk diet therapy. No benefit was observed from intramuscular injections of histidine monohydrochloride.

In none of the animals subjected to gastro-enterostomy did gastric, duodenal, or jejunal ulcers develop. A jejunal ulcer frequently developed, however, when pyloric or gastric exclusion had been performed. No lesions were observed in the isolated pyloric segment of the stomach, although definite ulceration occurred when acid-secreting mucosa was included in the isolated portion of the stomach.

From these observations and from studies of gastric secretion it would appear that gastric acidity is a factor in the experimental production of peptic ulcers by administration of cinchophen.

The Effect of Vitamin D on Intestinal Atony of Rickets*

By

LESTER YODER, M.S.

AMES, IOWA

IN previous reports (1) from this laboratory on studies of the action of vitamin D it was stated that intestinal reduction of iron in deficient animals was decreased by feeding vitamin D and that the surface tension of the intestinal juice was also decreased by calcifying doses of the vitamin. It appeared as if these effects probably could be brought about by any treatment which would decrease the time required for the passage of food through the digestive tract because a sharp temporary decrease of reduced iron in the feces of rachitic rats could be brought about by feeding effective doses of certain purgatives. This was consistent with the reports of Menville, Ane and Blackberg (2, 3), who, through the use of barium test meals and the roentgenoscope, found a decreased motility in parts of the gastro-intestinal tracts of rachitic rats. By a similar technique Harris and Bunker (4) found more recently that vitamin D deficient rations caused hypomotility in all parts of the gastro-intestinal tracts of rats and that supplements of the vitamin brought about greater motility. In this laboratory similar conclusions were reached by employing a different technique in an effort to determine the reason for the sudden change in intestinal pH and iron reduction produced in rats whenever a rachitogenic ration was supplemented with effective doses of vitamin D.

Young rats made rachitic by subsistence on the Steenbock ration 2965 were placed in individual cages and used in some comparisons between animals which were fed vitamin D and their litter mates which were not fed the vitamin. Vitamin D was added to the rachitogenic ration of representative rats of each of five litters in the form of Viosterol dissolved in carbon tetrachloride. After at least six days of vitamin therapy one per cent of lamp black was incorporated in the ration of both the deficient and the vitamin treated rats. After the rats had fasted for several hours the carbon ration was fed in portions at the rate of 2 g. per rat at intervals not to exceed the ordinary rate of consumption of the feed. The time of the first feeding of the carbon ration was noted and thereafter the time of the first appearance of black feces.

The Viosterol consumed varied from 2.2 mg. to 8.8 mg. per rat. From tests with many other rachitic rats 2.2 mg. of this preparation of Viosterol barely produced a narrow continuous line of calcification.

The data in Table I show one case in litter 90 where one of the 7 rats receiving the vitamin required slightly more time for the passage of the carbon than any of its rachitic litter mates. This rat would not eat regularly. In other experiments with vitamin D it was found that some animals finally refused to eat

TABLE I

Effect of the ingestion of Viosterol upon the time required for the passage of food through the digestive tracts of rachitic rats

the ration at the usual rate. Nevertheless, the average decrease per litter in time required for the passage of food through the digestive tracts of the rats due to the ingestion of the small amounts of vitamin D was 26 per cent. Since the larger additions of vitamin D to the animals of litter 312 did not induce a proportionate decrease in the time required for passage of the carbon, it seems there must be a minimal requirement of vitamin D by the digestive tract for a tonicity which can maintain either a decreased intestinal volume or increased motility. Thus, shorter digestion periods induced by the ingestion of vitamin D may account for the accompanying decreases in the intestinal reduction of iron.

The Effect of Vitamin D on Intestinal Iron Reduction*

By

LESTER YODER, M.S.

AMES, IOWA

IN feeding experiments with rachitic rats it was noted in this laboratory that vitamin D caused iron supplements to the rations to pass through the digestive tracts of the animals in a less reduced state. A reason for this action of the vitamin was recognized when it was found in this laboratory also that small amounts of vitamin D caused a significant decrease in the time required for the passage of food through the digestive tracts of rachitic rats (1). Apparently such a change in rate of passage of food prevents a rise in intestinal reduction intensities of sufficient magnitude to bring about the conversion of ferric iron to the ferrous state. The effect proved to be so general and so marked that the possibility of its use as a test for vitamin D was also investigated.

Due to the relation of oxidation-reduction and acid-base systems such a test probably would be a corollary of the decrease induced in the pH of the feces of rachitic rats following the ingestion of vitamin D. This effect on fecal pH was observed by Zucker and Matzner (2) who proposed and patented it as a test for vitamin D. That oxidation-reduction systems and acid-base systems are intimately related was shown by the physico-chemical researches of Clark and coworkers (3).

Bergeim (4, 5) published a method for the evaluation of intestinal putrefaction which involved the addition of a small amount of hydrated ferric oxide to the ration and a subsequent estimation of the ratio of reduced to total iron appearing in the feces. He used this ratio as an index in a study of the effect of various constituents of a ration on intestinal reduction and putrefaction.

In the work herein reported Bergeim's index of putrefaction or reduced iron determination was used in studying the effect of vitamin D upon intestinal reduction in rats. For purposes of comparison as criteria for ingested vitamin D parallel determinations of fecal pH and tests for bone calcification were also included.

METHODS AND RESULTS

Determination of reduced iron. As little as 0.05 gm. of intestinal residuum or feces was macerated in a short test tube 18 mm. in diameter with 6 c.c. of 12 per cent hydrochloric acid and heated in a boiling water bath for 40 seconds. The solution was then

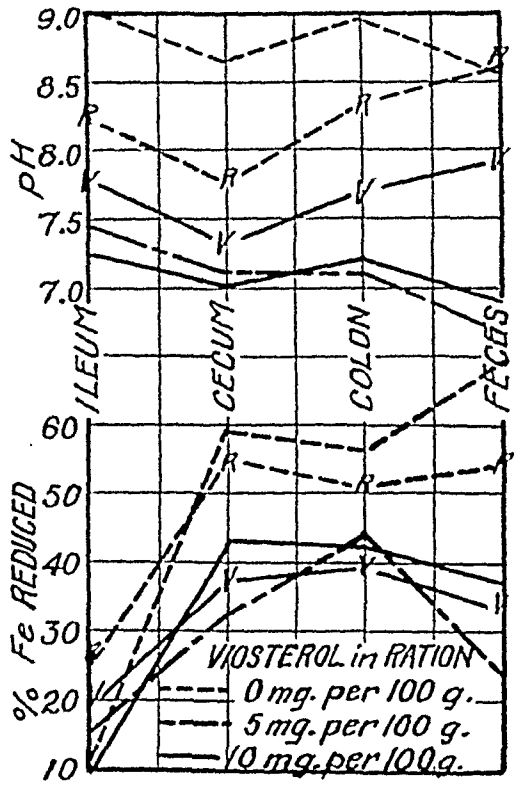

Fig. 1. Effect of vitamin D upon iron reduction and pH in the lower digestive tract of rats.

*Journal Paper No. J-366 of the Iowa Agricultural Experiment Station, Project No. 102.
Submitted September 29, 1936.

filtered through a long-necked funnel previously fitted with rapid filtering ash free 7 cm. filter paper. Two c.c. of the filtrate were pipetted into each of two 25 c.c. graduated cylinders. To one was added dropwise about 0.05 N potassium permanganate solution until the color no longer disappeared immediately. Usually 3 to 5 drops were required. Then to each cylinder were added 2 c.c. of 2 per cent potassium thiocyanate solution and enough distilled water to bring each to the same volume suitable for comparison in a colorimeter. The lower reading of the solution oxidized with permanganate divided by the higher reading of the unoxidized, multiplied by 100 and subtracted from 100 gave the per cent of the total iron which was reduced. This is Bergeim's index of reduction. The procedure gave for the unfed rachitogenic ration 1.0 per cent and for the same ration containing added vitamin 2.3 per cent of reduced iron.

pH was determined potentiometrically with the quinhydrone electrode and the saturated calomel electrode cell and corrected to 25° C.

The vitamin effect on intestinal reduced iron. Six litter-mate rats which had become rachitic on the vitamin D deficient ration were placed in groups of two each and fed, respectively, 0, 5 and 10 mg. of Viosterol per 100 gm. of the ration over a period of 20 to 30 days. They were then posted one at a time and the contents of the ileum, cecum and colon of each animal removed to determine immediately the pH and per cent of reduced iron. The results were averaged for each group and are shown in Fig. 1.

Four rachitic rats of another litter were divided into two groups, one of which was fed Viosterol at the rate of 10 mg. per 100 gm. of the deficient ration for only 3 days. These were then posted and the contents of the lower tracts likewise examined. The averaged results are shown on the diagram of Fig. 1 as lettered graphs, R and V.

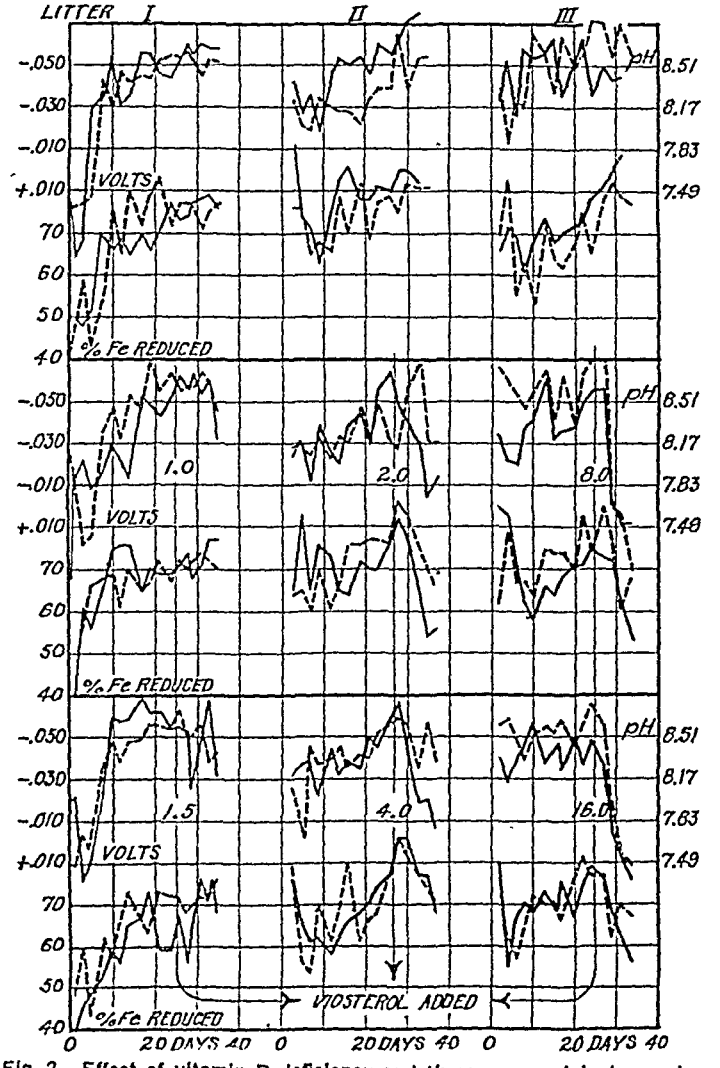

Fig. 2. Effect of vitamin D deficiency and therapy on quinhydrone electrode potentials and reduced iron in the feces of rachitic rats.

The results show that intestinal iron reduction rose from a small value in the ileum to relatively large values in the cecum and lower portions of the intestinal tracts of rachitic rats. Ingested vitamin D had little if any effect on iron reduction in the ileum but definitely brought about decreased reduction in the cecum, colon and feces. This decrease was the greatest in the feces. That 10 mg. of the Viosterol apparently produced a smaller decrease in intestinal iron reduction than 5 mg. is accounted for by the fact that this effect of the vitamin, after an extended treatment such as this, is not constant.

The vitamin effect on fecal reduced iron. In order to find the effect of the deficiency disease and its treatment with vitamin D upon the iron content of an ingested deficient ration it was desirable to determine the per cent of reduced iron in the feces of standard rachitic rats during incipient rickets and during treatment with various doses of vitamin. Sufficiently large doses of vitamin D would cause a "break" downward in a rising curve of per cent of fecal reduced iron. The rats could then be "line-tested" for bone calcification as usual and a comparison made of the relative minimum effective doses of vitamin necessary to cause a break in the reduced iron curve or a positive calcification in the "line" test.

Not only determinations of reduced iron but also determinations of quinhydrone electrode potentials were made on every sample of feces obtained throughout the test period. Graphs from the data, being the same as for the fecal pH change effect, were then directly comparable.

Changes in fecal reduced iron were studied in growing rats during the entire period of subsistence on the Steenbock and Black ration 2965 modified to contain 0.5 per cent of powdered hydrated ferric oxide. The animals weighed about 60 gm. when weaned and started on the rickets producing ration. All animals in each comparison were fed the same amount of ration in individual wire bottom cages. All tests were made on fresh feces obtained by digital pressure on the colon of the rats. Representative comparisons were made from 18 rats or three litters, I, II and III, of six rats each. From one to three days after the animals were started on the rachitogenic ration samples of feces were examined at once for effect on quinhydrone electrode potential and for ratio of reduced to total iron according to the methods already described. This routine was repeated every other day except Sundays on all rats until the experiment was terminated on the tenth day following the first additions of vitamin D to the diet. The experimental data were thus obtained over a period of 34 to 37 days. Two rats of each litter were fed no vitamin and the other pairs of rats were fed the vitamin in the form of Viosterol in doses of 1.0, 1.5, 2.0, 4.0, 8.0 and 16 mg. per 100 gm. of ration, respectively, beginning on the 25th or 27th day of subsistence on the rachitogenic ration. The Viosterol was a commercial 100 D preparation which, however, had a lower potency at the time it was used in these experiments.

The data are shown in the form of a graph for each animal in Figure 2. Since the voltage of the cell, composed of the quinhydrone and saturated calomel electrodes, bears a linear relation to pH, the graphs would be the same for both voltage and pH. The graphs show true changes in voltage or pH but actual changes in alkalinity were minimized by the graphs when high and exaggerated when low. However, it should be borne in mind that the values rose from a low alkalinity to a higher alkalinity as the deficiency disease progressed in the rats.

Iron reduction variations were similar to variations in pH and showed a rise from low percentage reduction to higher more constant values as rickets progressed.

As the dose of vitamin was progressively increased no "breaks" in these graphs due to the addition of Viosterol were noticeable until 2 mg. per 100 gm. of ration were administered. Then the pH or voltage graphs and iron reduction graphs both recorded the effects of vitamin in the ration. There was probably some effect recorded at the 1.5 mg. level by the pH or voltage graph. Increased dosage did not alter the nature of the "break" much; it merely occurred sooner.

Although the graphs clearly show the presence of vitamin D in the diet at 2 and 4 mg. levels, there was no evidence of calcification in the rachitic bones of these animals. The 8 mg. dose gave a narrow continuous "line" and 16 mg. a wider line of calcification. The changes in fecal iron reduction are quite generally of this nature as the application of such graphs to tests with many other rats has shown. The decrease in fecal reduced iron has also been produced with additions of irradiated ergosterol to the ration. Unirradiated ergosterol has no effect. Therefore it is a characteristic effect of vitamin D.

SUMMARY

By determinations of reduced iron in the feces and in various parts of the intestinal tracts of rachitic rats it was found that ingested vitamin D caused a distinct decrease in a high intestinal iron reduction characteristic of a rachitogenic ration containing added iron.

Determinations of reduced iron in the feces of rats during the onset of rickets and during vitamin D therapy gave variations similar to variations in pH. As supplements of the vitamin were increased from ineffective amounts it was found that sharp decreases in fecal reduced iron occurred before calcification.

SECTION IV—*Roentgenology*

The Importance of Preliminary Films in a Routine Examination of the Abdomen*

By

I. KLEIN, M.D.
NEW YORK, NEW YORK

PRELIMINARY films of the abdomen are a necessary aid in diagnosis, for they may show conditions which are not evident clinically. They may also confirm an uncertain diagnosis as well as assist greatly in determining acute conditions. Indeed, just as at the first sign of trouble in the thorax of a patient, chest films are taken as an efficient method of aiding the diagnosis, so preliminary films of an abdomen ought to be made as a routine procedure on a patient who gives a history of an abdominal complaint.

In effect, medical literature does offer certain references which have already pointed out the value of this procedure. However, most of this literature, which refers to preliminary films in diagnostic work, relates directly to one condition or another in which this procedure is helpful, for example, intestinal obstruction, echinococcus cysts, etc. Two books, recently published, discuss this subject in general (1). Still, there remains a vacuum in medical literature relative to preliminary films in all their possibilities in the diagnosis of abdominal disorders. It is our aim, therefore, to synthesize the research already available on preliminary films in reference to only one condition or system and to offer a generalized view of the subject as well as to stress the value of this method as a routine procedure.

Great emphasis has been placed on the use of preliminary films in diagnosing acute abdominal conditions. Their assistance in these conditions is so important that most of the literature dealing with the subject of preliminary films is in reference to acute conditions. For example, Singer has published a series of articles, which stress this point. He writes that "in connection with acute abdominal emergencies the roentgen ray finds its greatest field of usefulness in perforated ulcers" (2). Kraas makes a similar comment on preliminary films as they are used in cases of intestinal obstruction. "*In jedem Fall von zweifelhaftem oder ungeklärtem Ileus möchte eine Röntgenplatten Aufnahme ohne Kontrastmittel, womöglich in stehender Stellung, ausgeführt werden*" (3). These two opinions, selected from many similar statements, may serve to make clear that the use of preliminary films, taken in prone, erect and lateral views, in acute abdominal emergencies are of unmistakable diagnostic importance.

Moreover, as we have stated, preliminary films are of equal importance in correcting a faulty clinical diagnosis of abdominal conditions.

Thus:

Mr. M., a man of 55 years of age, was referred to us for a roentgen examination of his spine. He had been

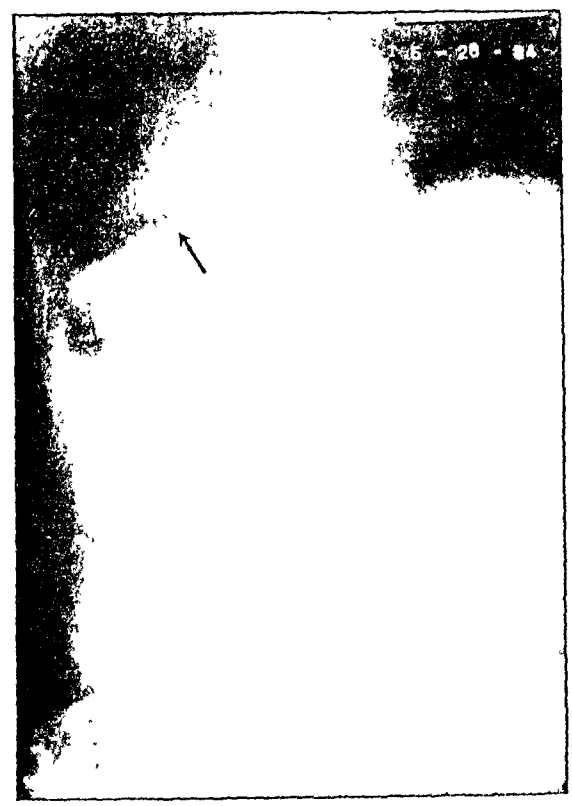

Plate 1. Film showing air under the diaphragm; result of perforated duodenal ulcer.

Received March 27, 1926.

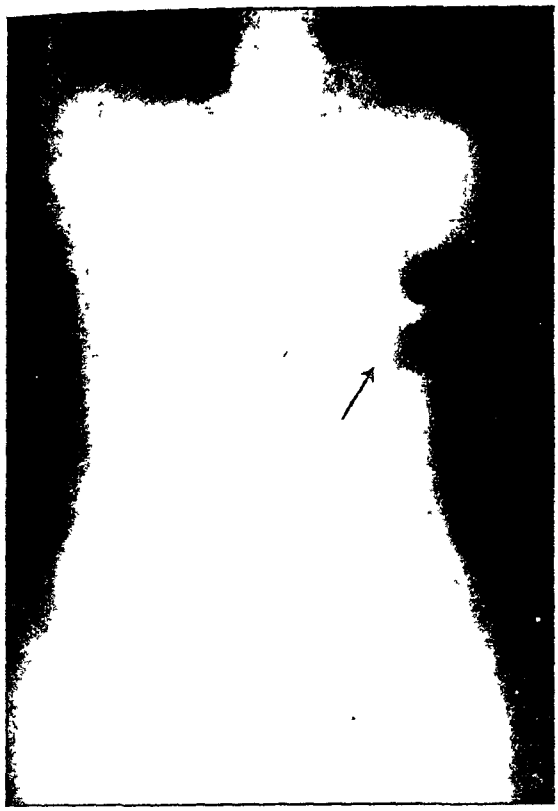

Plate 2. Film showing small bowel distension; result of intestinal obstruction.

complaining of a severe backache that lasted for some weeks. A preliminary film showed that an enlarged prostate, which had previously been diagnosed as benign hypertrophy, was malignant as there was a metastasis to his spine. Later findings confirmed this diagnosis.

Not only in acute abdominal conditions and in correcting a faulty diagnosis, as in the case we mentioned, are preliminary films found to be useful. They may also show conditions which are not at the time evident clinically.

In a roentgen examination, which was made of Mr. T., a man of over 40 years of age, who had sprained his back, we were able to note an adrenal tumor which had given no clinical evidence of its presence. It is certain, then, that the value of preliminary films of the abdomen as a triple aid to diagnosis is vital in various conditions.

These various conditions, which may be seen and diagnosed both as to their nature and location often in preliminary films, taken in various positions, may be briefly enumerated by us. We shall begin with conditions of the gastro-intestinal tract. Perforated ulcers may very often be diagnosed in preliminary films. Medical literature contains some references to this subject (4). We shall, therefore, add only a report of a case as an illustration.

Mrs. M., age 42, had a pain in her abdomen for seven hours. The pain was associated with retching and vomiting. It was very severe and sharp. There was no history of previous attacks. A clinical examination showed a rigid abdomen with a marked rebound tenderness. A preliminary film study revealed that there was air between the liver and diaphragm, a condition which is characteristic of a perforated ulcer in the gastro-intestinal tract. The patient was operated on immediately. The findings were a perforated duodenal ulcer.

The preliminary film is of equal importance in the diagnosis of intestinal obstruction. Ginsberg points out that preliminary films differentiate between a small and large bowel obstruction by showing the location of the lesion since small bowel obstructions are feathered, serrated and ribbed in appearance due to the valvulae conneventes, while large bowel obstructions are blunted and there are deeper indentations due to haustrations. Preliminary films of the intestines, then, may show not only an obstruction but its site as well (5). There is a large volume of medical literature which deals with this subject (6). We shall cite, nevertheless, a case to illustrate the use of a preliminary film study in this condition.

Mrs. K., age 44, was troubled for three days with nausea, constipation and pain in the abdomen. She had no relief from enemas. On examination her abdomen was not rigid; however, it was tender, and there was visible peristalsis over the right lower quadrant near an old scar. A preliminary film study showed air in the small bowel with a fluid level. The operation disclosed a small bowel obstruction caused by adhesions to an old appendiceal scar.

In the diagnosis of gall bladder and liver conditions, a preliminary film may also be of service. Hydrops of the gall bladder, calcified gall bladder, calculi, calcified liver abscess, and subphaenic abscess may be noted occasionally in a preliminary film study. Dr.

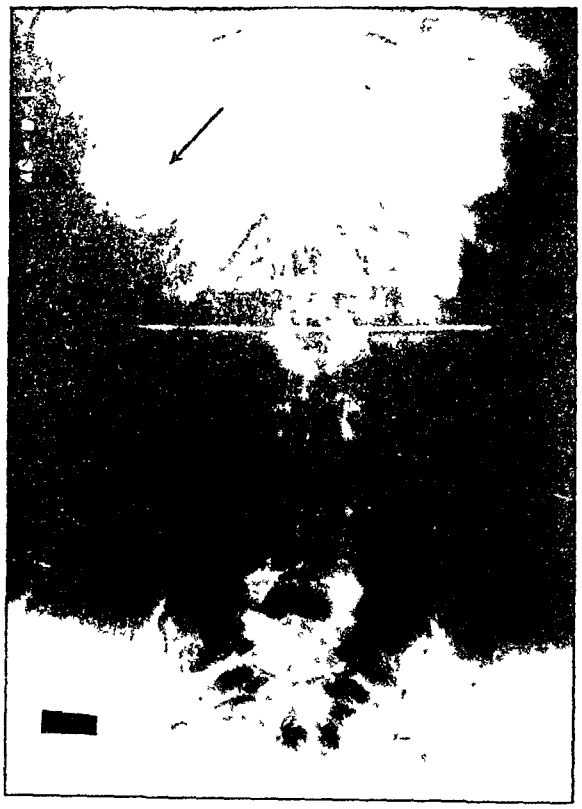

Plate 3. Film showing gall bladder calculi.

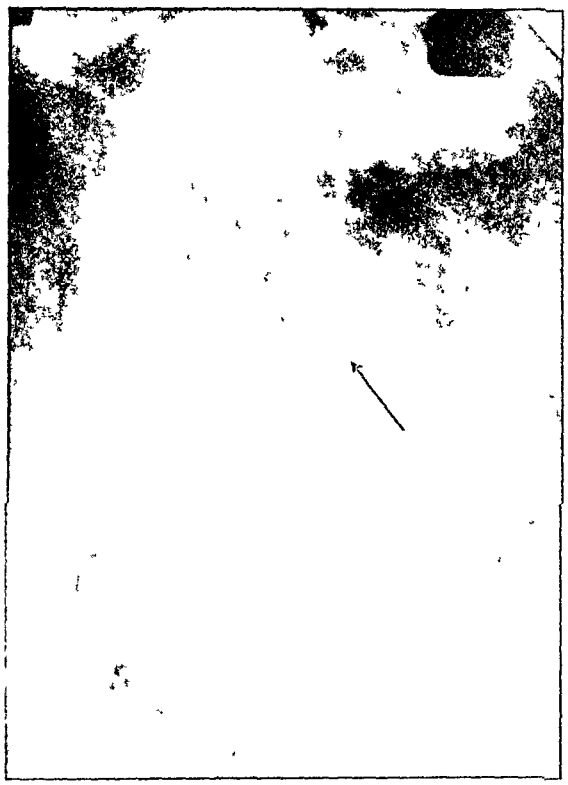

Plate 4. Film showing ectopic kidney with calculi.

Arnold described in an article how an echinoccocus cyst of the liver may be disagnosed either from indirect evidence, such as the displacement of adjacent organs, and occasionally, from direct evidence produced by the calcification of the cyst by the use of roentgenography (7). Gall stones may also show up on a preliminary film study without the use of a dye as in the following case.

Mrs. S., age 51, two weeks previous to our examination, was troubled by a sticky, scratchy pain in the left upper quadrant. She was treated at Harlem Hospital for pylonephritis. Later, she was transferred to City Hospital. An examination showed no masses or rigidity. However, there was tenderness in the right upper quadrant anteriorly and posteriorly. A preliminary film study revealed stones in the gall bladder. An operation confirmed the diagnosis.

In conditions of the urinary tract a preliminary film may also be of assistance. Such conditions as a stone in the kidney, bladder, calculus, a stone in the ureter, an ectopic kidney, peri-nephritic abscess, tumors of the kidney, polycystic kidneys and tuberculous or calcified kidneys may often be noted in a preliminary film These cases are useful as illustrations

Mrs. C., age 25, who had been delivered thirteen months previously of her first baby, was told at the hospital ten months ago that she had a tumor in the lower abdomen which was probably an ovarian cyst. However, this quasi-tumor gave rise to bilious attacks every two weeks with pain in the left side brought on by exertion. An examination showed a globular mass in the left lower quadrant which extended to the umbilicus. A vaginal examination showed that the mass did not extend into the left fornix. A flat film was made and revealed an ectopic kidney with a dendritic calculus in the pelvis. An operation confirmed these findings.

Mr. H., age 41, complained of pain, which had come on suddenly, in the right upper abdomen. The pain was intermittent and referred to the right thigh. It was followed by nausea and vomiting but he had no fever. An examination showed no masses, no tenderness and no spasms. A flat film revealed a stone on the right side. An operation gave evidence of a stone in the ureter.

Mrs. T., age 31, complained of a dull, aching pain at the right side below the costal margin. She had suffered nausea, vomiting and hematuria for a week. An examination of the patient, who was very obese, showed no tenderness on deep pressure in the right lumbar area. There were no masses felt. Her temperature was 102 degrees. A preliminary film revealed that the left kidney was normal, the right kidney markedly enlarged and its shadows were very irregular. There was complete obscuring of the psoas muscular markings on the right side. An operation showed an extensive peri-nephritic abscess.

In addition to the conditions, which we have listed above, preliminary films show the following: for example, enlarged spleen, in gynecological conditions, calcified fibroids, ovarian cysts and dermoid cysts; in obstetrics, for studies of the pelvic structure (8), abnormal pregnancies and multiple pregnancies as well as for normal pregnancies. And finally, to complete the list we must include the skeleton and its anomalies in reference to abdominal conditions, tuberculous bones, syphilitic bones, Paget's disease and primary and secondary malignancies and foreign bodies.

The technique of the preliminary film in relation to foreign bodies is of special aid since patients are often unable to remember or do not know that they have

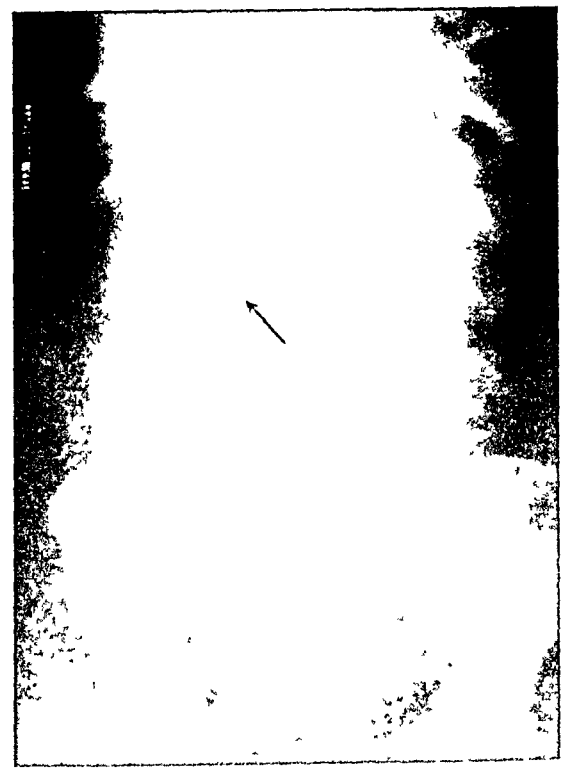

Plate 5. Film showing obscuring of psoas musculature.

Plate 6. Film showing foreign bodies.

swallowed a foreign body and their symptoms are not explicable clinically. However, preliminary films may often show the cause of the discomfort and its location as in the following case:

Miss H., age 11, a psychotic, was admitted to the hospital. She was complaining of a vaginal discharge. One month later she was bothered by pain in the right lower quadrant. This pain was accompanied by vomiting and loss of appetite. An X-ray examination revealed two safety pins and a common pin in her intestines.

SUMMARY

This brief outline of the preliminary film in reference to various conditions of the abdomen may serve to point out the intrinsic value of this procedure in diagnostic work. The preliminary film procedure is simple, without discomfort to the patient, and is a definite aid in diagnosing abdominal conditions which are not evident clinically. It may also serve as a means of controlling a faulty diagnosis and it can assist in designating the site of acute conditions. Because of this triple function of the preliminary film procedure, it is to be recommended as a routine procedure in all cases of abdominal complaints.

Carcinoma of the Tail and Body of the Pancreas

A Roentgenologic Technique for Its Demonstration

By

MORRIS A. HERSHENSON, B.S., M.D.

PITTSBURGH, PENNSYLVANIA

THE purpose of this communication is to describe a roentgenologic maneuver which is useful in demonstrating a tumor of the tail and body of the pancreas. The nature of the tumor, whether it be benign or malignant, can then be determined by the patient's clinical picture. In order to illustrate the usefulness of this roentgenologic procedure, a case is cited in which the diagnosis of carcinoma of the tail and body of the pancreas was established through its application. This example stresses the aid contributed by such X-ray information, since the recognition of carcinoma of this portion of the pancreas is only seldom accomplished prior to exploratory laparotomy or necropsy.

The pancreas does not lend itself to X-ray exami-

Submitted August 28, 1936.

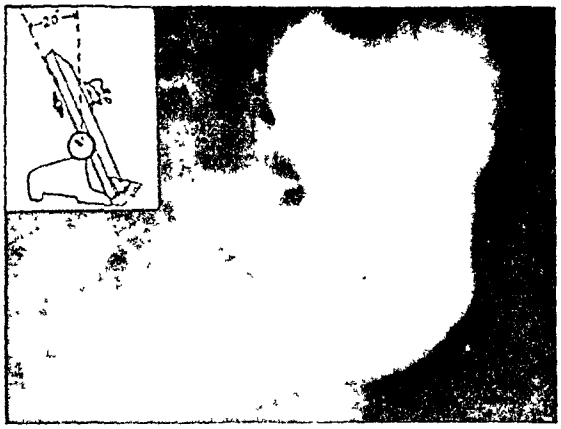

Fig. 1. The filling defect near the lesser curvature of the stomach is produced by the retrogastric mass. This film was made with the patient lying prone on the tilt-table, inclined to about 20 degrees from the vertical.

nation. Its specific density is not much different from that of the surrounding tissues; neither is there any suitable roentgen contrast material applicable to this organ. For these reasons, the gland cannot be directly roentgenographed. Perhaps, as by the injection of colloidal thorium salts the liver and spleen have been visualized, so too, some day a method may be discovered for rendering the pancreas radiographically opaque. But so far, its form may be studied by indirect means only. It can be recognized by such pressure changes as the pancreas exerts upon the neighboring stomach, duodenum, or colon, which, in turn, can be readily photographed by filling them with suitable contrast media.

There are three indirect roentgenologic signs of tumor of the pancreas. The first of these is the expansion of the shadow of the horse-shoe curve of the duodenum. Carthy (1) explained this as the result of tumefaction of the head of the pancreas, for it is in close relationship to the mesial surface of the curve of the duodenum. Carcinoma in this region, by its increasing size, presses back the duodenum and not only widens the "C" curve which the bowel normally assumes, but may even compress it. Gutman and Jahiel (2) testified to the value of this indirect sign and illustrated it by reporting their case of carcinoma of the head of the pancreas, which produced a widening of the duodenal curve and, in addition, showed invasion and stenosis of the duodenum.

Such obstruction of the duodenum is the second indirect roentgenologic sign of tumor of the pancreas. This obstruction or partial stenosis need not be limited to the portion of the duodenum lying close to the head of the pancreas. It may occur in the distal part of the duodenum, as well, if the tumor springs from the adjacent body of the pancreas. The case reported by Vorhaus (3) exemplifies such obstruction of the third part of the duodenum, due to carcinoma of the body of the pancreas.

The third indirect sign is that of extrinsic pressure exerted by a tumor of the pancreas upon the adjacent portion of the stomach. Such a filling defect of the stomach has frequently led to the erroneous diagnosis of gastric malignancy. The instances reported by Scholz (4, 5) are examples. Because of the irregular filling defect on the greater curvature, he diagnosed carcinoma of the stomach in each of his three cases. But postmortem examination showed that this filling defect had been produced by extrinsic pressure and by adhesions of the stomach to a carcinoma of the tail of the pancreas.

The pressure of the pancreatic neoplasm may not bring about a constant filling defect of the margin of the stomach. Instead, it may press upon the body of the stomach and distort it. In the case to be described, no such encroachment upon the stomach was observed when the patient was standing erect in front of the fluoroscope. Only when some pressure was applied to the anterior abdominal wall was there elicited any sign of a retrogastric tumor. Similarly, when the patient was bent backwards by partially lowering the fluoroscopic tilt-table, there was seen a filling defect of the body of the stomach, produced by the tumor in the pancreas. This observation suggested the following roentgenographic technique to demonstrate the presence of a mass behind the stomach.

RADIOGRAPHIC TECHNIQUE

The patient, after ingesting the usual barium meal, is placed erect against the vertically tilted X-ray table, his abdomen against the table top. Under direct fluoroscopic control, the table is gradually lowered until a point is reached where the stomach is pressed upon by the structures lying behind it. These are the spine, the abdominal aorta, and the body of the pancreas. Normally, no filling defect of the body of the stomach is noted until the table is tilted nearly to its horizontal position. Then one frequently sees the familiar localized compression of the middle of the stomach as it crosses the shadow of the lumbar spine. But when there is present a retrogastric tumor such as carcinoma of the body of the pancreas, then the filling defect of the stomach becomes noticeable much sooner. Figure 1 shows the degree of pressure on the stomach obtained by titling the X-ray table about twenty degrees from the vertical. At this angle, only a small filling defect is seen above the incisura angularis. When the table is lowered to about forty-five degrees, the stomach is more extensively compressed by the tumor of the pancreas behind it, as shown in Figure 2. Now, the filling defect extends trans-

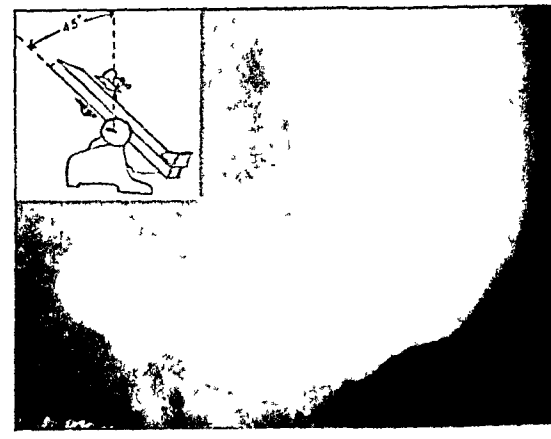

Fig. 2. With the tilt-table inclined to about 45 degrees from the vertical, the retrogastric mass now produces a filling defect of the stomach representing an area of compression extending towards the pylorus. Its form and location suggest a tumor of the tail and body of the pancreas.

Fig. 3. Post Mortem Examination: The pathologist's hand is grasping the large, hard tumor behind the stomach.

versely towards the pyloric end of the stomach. If the table were to be lowered to a horizontal position, with the patient lying prone upon it, the combined forces of the pancreatic tumor, the abdominal aorta, and the curve of the spinal column would then exert so much pressure upon the stomach as to cause its anterior and posterior walls to touch, thereby entirely expressing the opaque meal from its middle and no longer showing the extent of the retrogastric mass. Roentgenologically, this is as undesirable as is the appearance of the fully filled stomach when the patient is examined standing in the vertical position.

That the tumor mass producing the pressure is really extra-gastric and not a lesion of the mucosa of the stomach itself is proven by the presence of uninterrupted lines in the gastric mucosal pattern. This, too, can be revealed by the same procedure of tilting the table to the angle where, under direct roentgenoscopic control, there is obtained the desired amount of stomach compression necessary to bring out these gastric rugae. The neoplasm of the body of the pancreas will now act as the compression device for demonstrating the gastric mucosal topography.

DISCUSSION

Malignant neoplasm in the body and tail of the pancreas, but not involving the head of this organ, is really not rare. In a series of fifty proven cases of primary carcinoma of this gland, reported by Heck and Mortimer (6), this location of the growth was found nearly as often as was carcinoma of the head of the pancreas. But the clinical recognition of carcinoma of the body or of the tail of the pancreas is infrequent. Here the neoplasm does not encroach upon the extrahepatic biliary ducts and does not produce the obvious symptom of progressive, painless jaundice, such as it frequently does when involving the head of the pancreas.

In a recent issue of this Journal, Vorhaus (3) relates that, after reviewing the literature on the subject, he "could not find a single report of the clinical and roentgenologic findings which would enable such a diagnosis to be established." The case, which he correctly diagnosed as one of carcinoma of the body of the pancreas, he therefore believes to be the first of its kind to be reported. If that be so, then the one described here as a practical application of the recommended roentgenologic maneuver is the second reported case of carcinoma of the body and tail of the pancreas to be recognized by its clinical and roentgen pictures.

Fig. 4. The several small and one large area of metastatic carcinoma are seen on the under surface of the liver.

Fig. 5. The cut surface of the liver shows numerous islands of metastatic carcinoma.

CASE REPORT

The significant points in the history of this sixty-five year old white man were severe, sharp pain in the epigastrium, radiating to the left hypochondrium; his preference for sleeping in a sitting posture, or, even better, while leaning forward with his head and shoulders resting on a table, because, in this position, he had the least abdominal pain; the progressive loss of weight and strength; and the roentgenologic findings of a tumor mass behind the stomach.

He came to the office two weeks after the onset of pain in the upper abdomen, and related that food and alkaline powders made his symptoms worse. The pain was sharp and burning in character, and would radiate to the left hypochondrium. He had discovered that lying on his back accentuated the pain, and that sitting up or leaning forward diminished it. Hence, he elected the latter position for comfort. He would prepare for a night's sleep by pulling an easy chair against a table. Then he would place a pillow on the table, lean forward, and rest his head upon it. In this posture, he could find relief of the abdominal pain. There were no other important symptoms. There was no nausea nor vomiting, and there was nothing un-

usual in the character of his stools. He had lost fifteen pounds in the previous several weeks.

With this weight loss, the abdomen lent itself to satisfactory palpation. Nevertheless, no pathological masses could be felt at this time. The smooth liver edge was just below the right costal margin. Tenderness on moderate pressure was elicited in the epigastrium. Nothing unusual was observed or heard in the abdomen. There were no palpably enlarged lymph nodes in the groins, axillae, neck, or supraclavicular regions. The remainder of the physical examination brought to light no findings of pathological significance pertinent to this case report.

Of the laboratory studies performed at the office, the roentgenologic findings were of the greatest aid in arriving at the correct diagnosis. The X-ray revealed an area of diminished density in the mid-portion of the barium-filled stomach, which corresponded in location to the region of epigastric tenderness noted on physical examination. Yet no tumor mass could be palpated, even under direct fluoroscopic control. Moreover, this filling defect of the stomach was not due to any intrinsic gastric lesion, since there was no distortion of the gastric mucous rugae. Neither did the defect move along with the stomach when the latter was manually displaced. With the patient standing erect, the stomach shadow appeared evenly dense throughout. But as the tilt-table was inclined, a slight negative filling defect appeared along the lesser curvature of the stomach, above its *incisura angularis* (Figure 1). As the tilt-table was brought farther down, the defect extended over a greater area of the stomach, and pointed towards the pylorus (Figure 2). This roentgenologic finding was interpreted as due to a retrogastric tumor. Its anatomic location and extent led me to diagnose it as a tumor of the tail and body of the pancreas, clinically malignant.

The patient's condition became progressively worse. He developed more pain; he lost more weight; and he became weaker. Three weeks after the office examination just described, he was admitted to the Montefiore Hospital on the service of Dr. L. Wechsler. There he remained until his death, sixteen days later. At about the time of his admission, the tumor mass noted roentgenologically had so increased in size that it became palpable in the upper abdomen. The size of the liver had progressively increased also, and its edge was now distinctly nodular. He never showed any obstructive involvement of the biliary tract. He did not develop jaundice. Two weeks before his death, the icteric index was only plus three, and the bromsulphothalein test for liver excretion showed only 10% of the dye retained in the circulation one hour after its injection. His urine was always free of sugar. The blood sugar was 108 mgm. per 100 c.c., the N.P.N. 32, and the creatinine 1.3. Only shortly before his death did the N.P.N value rise to 50 mgm. per 100 c.c. of blood.

Permission for *postmortem examination* was limited to the abdomen only. The autopsy was performed by Dr. Yardumian, pathologist to the Montefiore Hospital. The following is a summary of his detailed report:

1. Adenocarcinoma of the tail of the pancreas with advanced degenerative changes and fibrosis.
2. Infiltration of the body of the pancreas by the same neoplasm. The head of the pancreas was not involved.
3. Metastatic adenocarcinoma of the liver with chronic hepatitis.

DISCUSSION OF FINDINGS

In addition to considering the roentgenologic technique which aided considerably in arriving at the correct diagnosis in this case, it would be well to summarize the other laboratory tests, and also the clinical symptoms and physical findings which contribute to the recognition of carcinoma of the pancreas, particularly of its tail and body.

First is the history of pain in the epigastrium, aggravated by the ingestion of a meal. Engel and Lysholm (7) refer to this as the "pancreatico-solar syndrome." They explain that this symptom of pain is due to irritation of the coeliac nerve plexus by the tumor of the tail and body of the pancreas. The weight of the food-filled stomach pressing against the coeliac plexus also increases its irritation and so elicits pain. Similarly, lying supine, or even leaning backwards, produces pressure against it. This leads to deep-seated epigastric pain, which may extend to the back and radiate as along the course of an intercostal nerve. It may simulate the segmentary pain of radiculitis. Heck and Mortimer (6) also mention the frequency of pain radiating to the back when the lesion is in the body of the pancreas. Recently, another illustrative case of such "pancreatico-solar syndrome" was described in "Case Records of the Massachusetts General Hospital" (8), in which the diagnosis of carcinoma of the body of the pancreas was determined at necropsy.

The physical findings are not typical. Eusterman and Wilbur (9) comment on the high incidence of palpable tumors in their series of eighty-eight cases. Yet the frequent mobility and variation in position of such tumors contribute to the difficulty of preoperative diagnosis. In the cases of neoplastic involvement of the head of the pancreas, this variability in the location of the tumor mass is most pronounced. In the instance reported by Hess (10), the tumor mass was in the right lower abdomen and freely moveable. On the other hand, no tumor may be palpable until relatively late in the course of the disease, as illustrated by the case reported here.

In the light of these rather inadequate subjective and objective signs, it is natural that one should turn to the laboratory for some aid. Such laboratory studies are directed to the investigation of this gland's function, and to the demonstration of a tumor in its form. The known functions of the pancreas are the liberation of its endogenous insulin, and the secretion of its exogenous digestive enzymes. Although the clinical deficiency of the former is readily recognized by the resulting hyperglycemia and glycosuria, yet such an occurrence seldom exists in carcinoma of the pancreas. As a rule, the neoplasm does not involve the Islands of Langerhans, at least, not until the destruction of the gland has become far advanced. The analysis of duodenal contents for the qualitative and quantitative determination of pancreatic enzymes seems a reasonable investigation, but in actual practice "the experience of most observers has been that the technical details of such methods (of examination) are too complicated and the information too meager and unsatisfactory to warrant their routine employment" (11). The recent studies on serum lipase reported by Comfort (12) showed positive findings in but fifteen out of forty-five instances of carcinoma of the pancreas. Hence, this examination, too, can be considered of contributory value in only about one-third of the cases.

The remaining laboratory procedure is the search for tumor changes in the form of the pancreas. This is accomplished by the roentgen studies already described in the preceding paragraphs.

CONCLUSIONS

1. The roentgenologic examination is a valuable laboratory aid in recognizing a tumor in the body or tail of the pancreas.
2. The indirect signs of such a tumor of the pancreas are the expansion of the horse-shoe curve of the

duodenum, obstruction of the duodenum, or a filling defect of the stomach produced by pressure of the extrinsic mass. Such a gastric filling defect need not be constant. Sometimes the tumor may not be large enough to produce much distortion of the stomach. Evidence of this retrogastric mass can then be elicited only when aimed pressure is applied to the anterior abdominal wall. To obtain such pressure, a roentgenologic technique is described here.

The patient, after ingesting the customary barium meal, is placed erect against the vertically tilted X-ray table, his abdomen against the table top. Under direct fluoroscopic control, the table is gradually lowered until a point is reached where the stomach is pressed upon by the structures lying behind it. These include the spine, the abdominal aorta, and body of the pancreas. When there is present a retrogastric tumor, such as carcinoma of the body or tail of the pancreas, the filling defect of the stomach becomes noticeable soon after the table has begun to be inclined. It again disappears when the patient is replaced in the vertical position. One must also observe the normal gastric rugae in this region which indicate that the tumor does not involve the stomach itself.

3. The value of this procedure is illustrated by the presentation of a case where its application made possible the correct diagnosis of carcinoma of the tail and body of the pancreas.

4. This case seems pertinent for discussion here because: (a). This location of the lesion is relatively not infrequent; (b). Any such laboratory aid as the roentgenologic technique suggested above should be welcome, since the recognition of carcinoma of the body of the pancreas is seldom accomplished prior to exploratory laparotomy or necropsy; (c). This is believed to be the second case reported where the clinical diagnosis of carcinoma of the tail and body of the pancreas was established on the basis of its clinical and roentgenologic signs.

SECTION V—*Therapeutics*

The Etiology and Therapy of Ulcerative Colitis*

By

ASHER WINKELSTEIN, M.D.

NEW YORK, NEW YORK

IT is not generally realized that ulcerative colitis is now a very common disease. We see approximately 125 cases yearly at Mt. Sinai Hospital. Typhoid fever, formerly so prevalent, is now a rarity. The cause of this apparent increase in the incidence of colitis is conjectural: (1) if it is related to the tropical diseases, the marked increase in amoebic and bacillary dysentery in this climate may explain it. (2) if it is primarily a functional disease, in the sense that neurogenic influences may render the colonic mucosa more susceptible to infection, one should point out that all of the functional or so-called "diseases of civilization" seem on the increase at present.

Certain features of the clinical course are worthy of emphasis. This disease, with its bloody and purulent diarrhea (rarely constipation), running a febrile (or afebrile) course, is essentially a chronic illness. It is characterized, like peptic ulcer, by spontaneous exacerbations and remissions. Recurrences are the rule. It is doubtful if a severe case of ulcerative colitis, belonging to the group with an undetermined etiology, ever recovers and remains well throughout life. It is indeed a serious malady. Some years ago, in a survey of a 10 year period at Mt. Sinai Hospital, I found that the medical mortality was 18% in the severe, hospitalized group.

Under the term "ulcerative colitis" are included three groups of patients: (1) those with amoebic colitis. (2) those with bacillary dysentery, and (3) ulcerative colitis of undetermined etiology. The differentiation of the indeterminate group from amoebic and bacillary dysentery is usually an impossible task at the bedside or by means of the sigmoidoscopic or radiographic evidence. It is a laboratory problem—often a very difficult and at times an impossible one to solve. Before entering into a further discussion of the etiology, a few interesting pathologic and radiographic features should be mentioned: (1) secondary

Submitted October 16, 1936.

polyposis is quite frequent (13%). (2) perforation occurs in 3% of the cases. Such perforations are often very insidious and always fatal. (3) the sigmoidoscopic, pathologic, and radiographic findings frequently do not correspond with the clinical state. (4) it seems probable, but by no means proved, that the following forms of colitis; viz., diffuse ulcerative colitis, localized ulcerative colitis, ulcerative ileocolitis, regional ileitis, and granulomatous localized or diffuse ulcerative colitis or ileocolitis, are all varied expressions of the same fundamental disease process. We have seen, not infrequently, the transition from one of these types to the other in the same case. This is particularly true of that type of diffuse ulcerative colitis which eventually leaves as a residue, a localized granulomatous lesion in the ileo-cecal region.

While it seems that all these diseases form one group, one type may be split off which probably is a separate entity, viz., regional ileitis of unknown etiology. This lesion, found by Dr. A. A. Berg in his operative material and described by Doctors Crohn, Ginzburg and Oppenheimer, is an inflammatory lesion involving usually the last 8 or 10 inches of the ileum, usually terminating abruptly at the ileocecal valve—with some proximal so-called "skip" areas—with mucosal ulcerations and marked mural thickening (chiefly submucosal fibrosis)—with inflamed lymph nodes—and with fistulae and stenoses. Clinically, it simulates ileo-cecal tuberculosis, cecal neoplasms, acute and chronic appendicitis, ulcerative ileo-colitis, chronic abscesses with fistula formation, and various degrees of intestinal obstruction. It can be diagnosed by the clinical picture plus careful radiographic studies of the small intestine. It is not a very rare disease—we have collected approximately 60 cases in Mt. Sinai Hospital in recent years. The diagnosis of this disease is of great importance since the complete excision of the affected part seems to cure the patient.

In discussing the difficult subject of the etiology of these ulcerative diseases of the terminal ileum and colon, it seems desirable in the present state of knowledge, to be very conservative and careful in the expression of one's opinions. While ulcerative colitis is a fairly definite clinical and pathologic disease picture, it is doubtful if it is an etiologic entity. It is chiefly because of certain technical difficulties in the laboratory that there exists so much confusion in the discussions of its etiology.

Our personal experience is that a small per cent of typical chronic ulcerative colitis cases are instances of amoebic colitis. Often it is extremely difficult to find the organism. Also, at times, the therapeutic test with emetine and carbarsone fails. Recently, using the urinary bladder punch through the sigmoidoscope we have found amoebae in the biopsied tissues in a few cases in which repeated stool examinations were negative. Another group, perhaps 20 per cent, which seem to be of unknown etiology are really specific, viz., bacillary dysentery. In discussing the relation of the bacillary dysentery group to the remainder, that is, those with an indeterminate etiology (the other 75 per cent), we encounter many difficulties. It should be admitted at once that the chronic bacillary dysentery resulting from acute epidemic bacillary dysentery may be indistinguishable from the ulcerative colitis sporadically encountered. Although, after epidemics of bacillary dysentery some 2½ to 5% become chronic ulcerative colitis cases (often without any evidence of bacillary dysentery except the historical), nevertheless, it does not seem correct to assume that all, or even a large per cent of the ulcerative colitis cases of unknown etiology, are chronic bacillary dysentery. Even if one would like to feel that non-specific ulcerative colitis and chronic bacillary dysentery are one and the same, the evidence, as we shall shortly point out, is lacking for the establishment of this point of view.

For several years, under the direction of Gregory Shwartzman, Hershberger and Winkelstein (1) have been studying the relationship of indeterminate ulcerative colitis to bacillary dysentery. We studied a consecutive series of cases of sporadic ulcerative colitis patients in the wards of the hospital, chiefly in the years 1929 to 1933, for dysentery organisms, for dysentery agglutinins in the blood, and for dysentery bacteriophage in the stool. We found that 7 cases (11%) of typical "non-specific" ulcerative colitis had the organisms of bacillary dysentery in the stools; that approximately 20% had agglutinins for dysentery organisms in a titre above the normal expectancy (the normal expectancy of agglutinins for the Flexner strain is 1:100, for the Shiga, 1:50, and for the Sonne-Duval, 1:20) in the blood; and that 15 or 36% of 41 consecutive cases had a bacteriophage in the stool specific for one or another strain of the dysentery organisms. Forty-five consecutive controls, including several miscellaneous diarrheas, did not reveal an anti-dysentery bacteriophage in their stools. We concluded, with considerable caution, that this is suggestive evidence of a possible relationship in some of the cases of ulcerative colitis to bacillary dysentery. It is now necessary to explain why we were so careful in our conclusion about this relationship. We will first point out the difficulties in concluding from the laboratory data about the agglutinins, bacteriophage and even the organism, that chronic ulcerative colitis is acute or chronic bacillary dysentery.

Agglutinins for dysentery organisms, while usually not of a very high titre, may occur in the blood of normal people. Often exercise, a fever, or an unrelated disease (for example, typhoid fever), may bring out dysentery agglutinins. The mere finding of agglutinins in the blood is not diagnostic of bacillary dysentery. Cross agglutinins from closely related bacteria (B. Coli) may also confuse the situation. Agglutinins may appear and disappear rapidly, or, may appear late, or, may not appear.

While it is true that a bacteriophage for dysentery organisms may appear in the stool in patients as they are recovering from bacillary dysentery, this is not necessarily associated with the dysentery organism. A bacteriophage adapted to a Gram-negative organism in the gastro-intestinal tract may readily become adapted to several other organisms of the same group.

In practically every stool there may be a weak bacteriophage for the B. Coli. This bacteriophage may, at times, become strongly lytic, not only for the harbored B. Coli, but also for closely related stock dysentery organisms. The mere finding, then, of a dysentery bacteriophage in the stools of a patient with ulcerative colitis does not prove that the patient has or has had an infection due to the organisms of bacil-

lary dysentery. It may possibly signify such a state, or, it may signify a different or changed strain of B. Coli. Our statistical evidence, i. e. the finding of a dysentery bacteriophage in a fairly high percentage of the cases of ulcerative colitis of undetermined etiology and not in normal and miscellaneous controls, is, however, somewhat suggestive of the dysentery origin of the disease but,for the reasons just cited, not conclusive evidence.

Finally, the strongest evidence comes up for discussion, viz., the finding of dysentery organisms in the stools. The identification of the organisms requires great care. The cultural characteristics alone are insufficient. In fact, using the cultural characteristics alone for diagnosis, one would be forced almost each day to report atypical B. Coli obtained from various sources (gall bladder, genito-urinary tract, normal stools) as dysentery organisms. The agglutination in high titre of the organism by specific sera is absolutely essential for the diagnosis of an organism as a bacillary dysentery strain. Not only do these considerations from the laboratory offer obstacles but there are other serious objections to the idea that chronic bacillary dysentery and ulcerative colitis are identical. Ulcerative colitis is usually sporadic; bacillary dysentery is usually epidemic. Ulcerative colitis is almost never encountered as a contact disease; nor do certain geographical localities furnish more cases than others. Ulcerative colitis usually begins insidiously; bacillary dysentery is as a rule acute and stormy in its onset. Dysentery attacks all ages, particularly children, while ulcerative colitis usually hits young adults. As already pointed out, the pathologic, sigmoidoscopic, stool, and radiographic features of any chronic ulcerative colitis (amoebic, bacillary, or, indeterminate) may be identical although the etiology differs. This, of course, is probably due to the importance of the secondary invaders in the chronic stages of these diseases.

Our opinion in the matter of the etiology of chronic ulcerative colitis may be summarized as follows: (1) a small per cent are unrecognized amoebic colitis cases. (2) a certain per cent, approximately 20%, are instances of chronic bacillary dysentery in whom either the dysentery organisms or the secondary invaders, or both, keep up the disease. (3) the cause in the remainder is as yet unknown. What Bargen has described is probably a group of secondary streptococcic invaders. Three theories seem most plausible: (1) a primary functional (neurogenic) disturbance of the bowel and then a secondary infection. (2) the mucosa is first sensitized by a transient specific or special infection and then local or distant organisms or toxins attack the susceptible tissues (Shwartzman). (3) the specific cause, whether bacterial or virus in nature, is yet to be discovered.

We may now leave this discussion of the etiology and take up some of the therapeutic measures in the group of patients with ulcerative colitis of undetermined etiology. It is necessary to emphasize that we do not know the etiology in this group. Therefore, an ideal therapy, based on the cause and mechanism involved, cannot be realized. In the light of our present knowledge, we are forced to conclude that it is not an etiologic entity and we must base our therapy on the most rational concepts. These we have already outlined.

Some of the fundamental principles of therapy which should be kept in mind are: (1) this is a chronic disease with sudden spontaneous remissions and exacerbations. Great care, therefore, must be exercised in the interpretation of therapeutic results. (2) in view of the close relationship of the vegetative nervous system to the alimentary canal, all sorts of factors, particularly psychic and reflex, may play an important role. (3) in presenting therapeutic studies a sharp definition and clear differentiation of the group of patients under treatment should be stated. Obviously, it is a matter of great importance as to whether we are treating mild, moderate, or severe cases of ulcerative colitis. The mild cases perhaps require only rest, fresh air, sunshine and a good diet, i.e. hygienic therapy. In this discussion we are considering the more severe cases or so-called "colitis gravis,"—the in-bed, hospitalized group with fever, with bloody and purulent diarrhea, with severe ulceration, with advanced radiographic changes, with emaciation, anemia, and toxicity. (4) therapeutic results which are not interpreted and presented in the light of a complete study, viz., clinical, sigmoidoscopic, stool, and radiographic features, are not worthy of attention. (5) to claim the value of any single therapeutic measure, it must be used in a large group of cases of the same type and a striking, sudden, dramatic improvement must take place, within a few days to two weeks, in most of the cases so treated. Otherwise the improvement may be merely coincidental. (6) individualization in the treatment, good nursing, therapeutic resourcefulness, excellent clinical judgment, and, fine psychotherapy are highly desirable in the treatment of this disease.

Having stated most of the fundamental principles we may now consider separately the various therapeutic measures:

I. *Rest in bed.* This must be for a long period. Patients and their families must be warned of the prolonged, chronic nature of the malady. Occasionally, in the milder, chronic cases a change from bed to the open air and sunshine will produce a remarkable and rapid improvement.

II. *Diet.* The diet which I have instituted on the wards of Mt. Sinai Hospital in the treatment of ulcerative colitis is given here.

DIET FOR ULCERATIVE COLITIS USED IN THE MOUNT SINAI HOSPITAL, NEW YORK CITY

Breakfast:

Orange juice or grapefruit juice
Stewed fruit (strained)
Eggs—soft or hard boiled or poached
White bread or toast with butter or jelly
Buttermilk, thin cocoa, or tea.

Noon Meal:

Small portion scraped beef or lamb, lamb chop, fish, minced white meat of chicken (not fried)
Boiled, mashed, or baked potato
Strained asparagus, carrots, string beans, spinach, tomatoes, peas
Stewed fruit (strained), as pears, peaches, applesauce, ripe banana, custard, junket, jello
White bread or toast with butter or jelly
Buttermilk, thin cocoa, or tea
Tomato juice.

Supper:

Milk soup with strained vegetables, or clear soup
Eggs—soft or hard boiled, or poached
Small portion cream or pot cheese
Well-cooked cereal with milk and sugar or strained vegetable as above
Stewed fruit (strained), ripe banana, custard, junket, or jello
White bread or toast and butter
Buttermilk, thin cocoa, or tea.

It is well-balanced in protein, fat, and, carbohydrate. Milk is usually not well tolerated. Some observers have claimed that there is a primary or secondary avitaminosis, or, a "deficiency" state in the disease. While the evidence for this is not strong, it seems theoretically desirable to give Haliver Oil, Viosterol, yeast, cevitamic acid, ultraviolet rays and calcium. We have not seen any striking results from vitamin-rich foods or the administration of these substances, yet we continue to use them.

III. *Diarrhea.* The bowel movements are actually sanguino-purulent discharges rather than diarrheal stools. Hence the fallacy of most of the therapeutic measures which are directed against true diarrheas. Opium is the best drug, particularly when given at night to insure rest. Atropine, kaolin, and bismuth usually do not help very much. I have recently received from Dr. A. Koenig, of the Mellon Institute of Industrial Research, a vegetable gum rich in bassorin, which, taken in the form of a mucilage (a teaspoonful in a glass of water t.i.d.) by mouth, seems to increase the consistency of the stools, and, in some instances, clinical improvement. Substances like carob gum used similarly also help but apparently to a lesser degree. Often cleansing enemas (normal saline or 1% bicarbonate of soda), heat to the abdomen, and rectal installations of warm olive oil (with or without a teaspoonful of bismuth subcarbonate or subgallate) seem of value in the control of rectal discharges, tenesmus, or, discomfort.

IV. *Colonic Treatments.* A. *General.* The use of colonic irrigations, enemas, and rectal instillations is of doubtful value. They may spread infection. Some patients cannot tolerate them. Bicarbonate or saline enemas as stated may be cleansing and thus lessen the discharges. In chronic, sluggish ulcerative states, 1% tannic acid or silver nitrate (1:5000 or 1:2000) enemas may stimulate healing. Olive oil with bismuth subgallate as a rectal instillation may sooth an irritable rectum and sphincter.

B. *Antibacterial.* During the last 2 years we have had some interesting experiences with a new chlorine compound, "Azochloramid." This is an organic chloramine discovered by Schmelkes and collaborators (2, 3, 4), accepted by the Council on Pharmacy & Chemistry (5, 6). It is distinguished from other chlorine compounds by the slow rate with which the chlorine is liberated, permitting the preparation of stable solutions which retain active chlorine for considerable periods of time, even in the presence of such organic matter as pus or fecal matter. The chlorine is liberated from this compound so slowly that its solutions are odorless and a solution of azochloramid in olive oil (1:2000) such as I have utilized in my clinical work is applicable to the colonic mucous membrane without causing undue irritation. Due to the variety of the bacterial flora in the human intestine, antiseptic treatment would seem to have the best chance of success if a substance of non-selective bactericidal properties is used. Laboratory findings suggest that azochloramid should have such an effect.

I have therefore used azochloramid in olive oil (1:2000) as a rectal retention instillation (III to VI b.i.d.) in 25 cases of indeterminate ulcerative colitis. In somewhat more than half of these cases good results were seen. Within ten days there was subjective and objective improvement. Irritation was rarely encountered. In one case, acutely and severely ill for 1 year, where all other measures had failed, a brilliant result was obtained in 2 weeks with the use of this preparation. It seems worthy of careful clinical trial.

V. *Transfusions.* The use of fairly large (500 c.c.) repeated blood transfusions is perhaps the single most important therapeutic measure in this disease. Following a transfusion, one witnesses occasionally, a sudden, dramatic improvement, almost in the nature of a crisis. How such a result is brought about is only conjectural. Certain human sera may be strongly antitoxic to whatever toxins or viruses are responsible for the illness.

VI. *Specific measures.* Insofar as the etiology of the disease is not definitely established, the seeming multiplicity of specific etiologic factors makes the use of more or less specific measures desirable. The specific measures may be discussed under the following headings: (a) anti-amoebic; (b) anti-dysentery; (c) Bargen's serum; (d) vaccine therapy; (e) antitoxic B. Coli horse serum; (f) bacteriophages; (g) foreign protein shock.

(a) *Antiamoebic therapy.* Even if the organism is not found, we, nevertheless, institute a course of antiamoebic therapy. We feel that emetine hydrochloride, grs. 1 intramuscularly, daily for 10 days, together with carbarsone (0.25 gm. b.i.d for 10 days) is a good therapeutic test. Anayodin often causes an increase in abdominal discomfort and diarrhea and its use does not seem indicated as a therapeutic test. (In proved amoebic colitis, it seems very valuable). It must be admitted that we have rarely seen a striking result in the cases of undetermined etiology with this form of treatment.

(b) *Anti-dysentery measures.* When there is evidence at hand indicating strongly that the case is probably one of bacillary dysentery (i.e., the finding of the organism, a very high agglutinin titre, together with a potent anti-dysentery bacteriophage), polyvalent anti-dysentery serum should be used. It is necessary to have a serum which is strongly antitoxic and to administer it in very large doses within a short period of time. We have treated some cases in this fashion (giving within 3 days 350-400 c.c. of serum intravenously in divided diluted doses by the drip method) and we have seen some brilliant results. We have not been impressed with the results of the rectal instillations of anti-dysentery bacteriophage. Dysentery vaccine and toxin for immunization have not been tried.

(c) *Bargen's serum.* It is quite probable that some of the streptococcus strains play a rôle as secondary invaders. In view of our experience that large doses of serum seem desirable, it is possible that the use of Bargen's serum in very large doses intravenously might conceivably give better results than we have seen in a moderately small series of cases treated with

small doses of Bargen's serum subcutaneously and intramuscularly.

(d) *Antitoxic B. Coli horse serum.* On finding that the B. Coli has a powerful, soluble exotoxin, Gregory Shwartzman prepared an antitoxic horse serum using pooled strains of B. Coli and B. Coli toxins. This serum was strongly antitoxic as measured by the Shwartzman phenomenon (35 to 75 "phenomenon neutralizing" units per c.c.). As mentioned above, the experimental evidence provided by the Shwartzman phenomenon points to a possible concerted pathogenic effect of unrelated micro-organisms or their soluble toxic products. On the basis of this evidence, the idea occurred to me that the colon bacillus may be a very important primary or secondary invader in ulcerative colitis and therefore we instituted the antitoxic B. Coli horse serum therapy of nonspecific ulcerative colitis. (This therapy has been reported (7) elsewhere but a brief resumé will be given here). In the last year and a half 35 cases have been treated with this serum.** Only severe cases with toxicity, fever, bloody and purulent diarrhea and severely ulcerated bowels were selected for this therapy. If careful sensitization tests (conjunctival and intradermal) were negative, the serum (350-400 c.c.) was given, diluted in saline, in divided doses, using the slow intravenous drip method, spread over 2½ to 3 days. Preceding each intravenous injection, adrenalin was given. Immediate shock, chills, or sharp temperature rises were not encountered. Serum sickness occurred 5 to 10 days later. In 28 cases the results were strikingly good. In a few days to 2 weeks the temperature became normal, the stools were reduced to 1 or 2 formed movements, the mucosa healed, and the patient gained weight. In 3 cases, the patients improved after several weeks. In 4 cases, there was no improvement. Considering the type of case treated, these results are very encouraging. No conclusions should be drawn from this about the relation of the colon bacillus to ulcerative colitis. Intensive studies are being carried on now in our laboratory by Shwartzman, Hirshberger and myself, on the colon bacillus, its toxin, the preparation of new sera, the preparation of concentrated sera, and the possible specificity of certain strains of B. Coli found in ulcerative colitis. Immunologic studies with B. Coli toxin and antitoxin in animals and humans, in ulcerative colitis and other diseases, are also in active progress.

(e) *Vaccine therapy.* Our experience with Bargen's vaccine and vaccine filtrate is too limited to permit of presentation. The results of autogenous vaccines which were given routinely in a large number of the chronic cases, are difficult to evaluate. From our previous discussion of the rôle of the colon bacillus, it is obvious that it may be possible soon with further immunologic studies to quantitatively estimate and increase the B. Coli antitoxin in patients using B. Coli vaccine and B. Coli toxin. This is now being attempted on our colitis patients using skin tests and the Shwartzman phenomenon in the estimate of the antitoxic effects.

(f) *Bacteriophage.* While the results of the rectal instillation of anti-dysentery bacteriophage have been disappointing, it is possible that B. Coli bacteriophage (perhaps against certain specific strains found in ulcerative colitis patients) may prove more helpful.

**The antitoxic B. Coli serum work was made possible by a grant from The Friedsam Foundation which is gratefully acknowledged.

(g) *Foreign Protein Shock.* The explanation of our success with serum therapy (either anti-dysentery or anti-B. Coli) is probably not foreign protein shock, since, as already stated, we did not produce shock in our cases. We have utilized in a few cases intravenous typhoid vaccine to evoke chills and fever, without beneficial results. We are now undertaking a study of the effect of artificial hyperpyrexia on this disease.

(h) *Surgical therapy.* Surgical therapy for ulcerative colitis is indicated only under certain conditions. The indications are, briefly, four:

(1) for perforation, obviously.

(2) for localized, hypertrophic lesions which, wherever possible, should be completely removed, preferably with a preliminary anastomosis (ileo-colostomy).

(3) In the acute, septic, fulminating cases with a rapid downhill course, ileostomy may prove a life-saving measure. The type of case and the time of the institution of this form of surgical therapy requires rare clinical judgment.

(4) Where severe complications exist in the chronic, intractable cases such as strictures, polyposis, perirectal sinuses and suppuration, peri-sigmoid suppuration or massive hemorrhages, ileostomy should be instituted.

Appendicostomy, cecostomy, ileosigmoidostomy, partial or complete colectomy may be mentioned only to be condemned. The results are poor and the risks too great.

There are also strong objections to ileostomy. It is difficult to decide when to operate. The immediate mortality is high and the late mortality is considerable. It does not cure the disease. Even septic attacks occur in the presence of the ileostomy. In most instances, it must be permanent, for, if removed, the colitis recurs in a very severe form. A few years ago I sent a questionnaire to the leading surgeons and gastro-enterologists of the United States concerning ileostomy. The answers to the questionnaire giving information about 186 cases with ileostomy for ulcerative colitis bear out the impressions herein stated. In those cases—not an inconsiderable number—where the lesion is chiefly in the proximal colon (and terminal ileum) and where the rectum and sigmoid are normal or nearly so, Dr. A. A. Berg has suggested and used low ileosigmoidostomy with transection of the sigmoid closing the distal end and leading the proximal cut end of the sigmoid externally as a sigmoid colostomy. This procedure may prove valuable as such or as a preliminary operation to a later partial colectomy.

SUMMARY AND CONCLUSIONS

Ulcerative colitis is now a common disease, characterized by a chronic, recurrent course. Its clinical and pathologic features do not distinguish it from the specific colitides. Etiologically, it does not seem to be an entity. A few cases are unrecognized amoebic colitis. A larger percentage (perhaps 20%) are chronic bacillary dysentery. The etiology in the remaining majority is unknown. It may be that the ileocolic tissues rendered susceptible or vulnerable by a previous specific infection may be attacked recurrently by local or distant bacteria or their soluble toxic products, or, that the specific causative agent has not as yet been discovered.

In discussing the therapy in the indeterminate group the occurrence of spontaneous remissions should

always be borne in mind. In considering the conclusions presented about specific measures, the exact degree and the nature of the illness in the cases under treatment should be stated. The most valuable therapeutic measures seem to be: (1) Prolonged bed rest. (2) a full diet rich in vitamins and minerals. (3) opium and gums for the diarrhea. (4) saline, tannic acid, and silver nitrate enemas. (5) olive oil and Azochloramid rectal instillations. (6) repeated blood transfusions. (7) routine anti-amoebic therapy (emetine and carbarsone). (8) in proved cases of bacillary dysentery, massive doses of anti-dysentery serum. (9) in the cases of unknown etiology, antitoxic B. Coli horse serum (good results are herein reported with this form of therapy). (10) in the chronic, recurrent cases, active immunization with B. Coli vaccine and toxin in the interval stages. With reference to the surgical therapy, it may be stated that it is rarely indicated. In fulminating cases or in those with severe, chronic complications, ileostomy seems to be the best surgical procedure. For ileocolitis, where there is chiefly proximal colon involvement, ileosigmoidostomy with proximal sigmoid colostomy, preliminary to subsequent partial colectomy (Berg) seems to be a rational operative method worthy of trial.

In conclusion, we are impelled by our experience in recent years to revise our former pessimistic attitude concerning the prognosis in the severe cases of ulcerative colitis. Using the therapeutic measures herein described, there is apparently a decreased mortality and an improved clinical course in many cases.

SECTION VII—*Surgery of the Lower Colon and Rectum*

The Variety and Distribution of Gross Lesions in Lymphopathia Venerea*

By

COLLIER F. MARTIN, M.D., F.A.C.S.
PHILADELPHIA, PENNSYLVANIA

IN the limited time assigned for this paper, it is obviously impossible to go into any large amount of detail. In selecting the title "Lymphopathia Venerea" I am using one which I consider more appropriate than "Lymphogranuloma Inguinale" which unfortunately has been so often confused with "Granuloma Inguinale," a skin disease, and with "Lymphogranulomatosis," which is another name for Hodgkins disease.

So much has appeared in literature in recent years that I must pass up any historical references, aside from the fact that in 1811 Thomas Copeland suspected the venereal origin of stricture of the rectum, and in 1859 Chassaignac spoke of a "peculiar inguinal node infection." In 1913 Nicholas, Durand and Favre recognized the condition as a pathologic entity and in 1922 Nicholas and Favre first used the name "Lymphogranuloma Inguinale" in place of the name "Nicholas-Favre disease." In 1925 Wilhelm Frei devised a specific skin test for this disease. In 1932 Wolfe and Sulzberger suggested the name "Lymphopathia Venerea" as being descriptive and avoiding much confusion in literature.

Lymphopathia venerea is probably a disease of great antiquity, and has been pretty well distributed over the world. One cause of confusion has been the difference in the manifestations in the male and female. In the male there is a primary penile sore, followed by a bubo, which may, or may not suppurate following the initial lesion. In the female the primary sore being situated in the vaginal wall or upon the cervix, is rarely if ever seen, while the predominating pathology is a stricture of the rectum. These differences have led us far astray in recognizing these two conditions as one and the same disease. In our experience 90% of the females are afflicted with rectal stricture, while only 10% involve the genitalia and inguinal glands. In the male these figures may be reversed, but in either sex both may exist simultaneously. The outstanding factor is also the marked difference in the expression of the disease in the white and the negro races. I am thoroughly in accord with Rosser, who in 1922 stressed the fibro-plastic diathesis in the negro race, showing that there was a marked tendency of all injured and infected tissue to develop thickening, pseudo-elephantiasis and keloidal degeneration or formation. Years ago I used the term "negromata" in describing this tendency to inflammatory tumor formation. In the white race we do have stricture formation, hypertrophies and pseudo or

*Read before the Annual Session of the American Proctology Society, May 11, 1936, Kansas City, Mo.
Submitted August 2, 1936.

Plate No. 1

real elephantiases, but these conditions are not so pronounced as in the negro race. Intermittent attacks of lymphedema with much less inflammatory reaction, seem to be more prevalent.

In any case and in either race, this disease runs a very irregular course, the symptoms and indurations subsiding to such an extent that cures have been reported, only to have the disease flare-up at varying intervals. I am extremely skeptical as to any permanent cure of this disease. Laboratory examination of the tissue frequently confuses us with reports of a chronic inflammation, lues, or tuberculosis. Two or three different reports may be made upon the same tissue by different laboratories, or upon the same patient in the same laboratory at different periods. Fortunately the Frei test will clear up the diagnosis, although lues, tuberculosis and other diseases may be associated. Particularly is this true in the colored race, which seems to enjoy acquiring a multiplicity of venereal infections.

As these cases are constantly visiting our clinics, persistently hospitalized, and everlastingly in a state of poverty, the cost to the community is an important, economic factor. As many of them work in restaurants and kitchens of private homes, certainly notice should be taken of the peril of spreading this infection. Our Philadelphia group of proctologists, assisted by

Plate No. 2

some of our urologists and dermatologists, has contacted about 360 cases in four and one-half years. Naturally in the proctologic clinic, the majority of the cases present the picture of rectal stricture. 90% of these are women, but after we interpret the studies made by Batson and Nesselrod upon the lymphatic circulation of the genito-ano-rectal area, we can see how it is possible that both sexes may be susceptible to all of the complications possible in this disease. I am endeavoring to call attention to the rather bizarre pathology. The various expressions of this disease may be noted as a bubo which may, or may not, look as if it had been operated upon, a urethral stricture, a rectal stricture, esthiomene and elephantiasis, multiple fistulae, recto-vaginal fistula or any combination of these.

We have come to the conclusion that when we encounter a condition in the genito-ano-rectal area that looks like nothing we have seen before, that looks like no other disease, that does not even look like itself, that we had better perform a Frei test to help clarify the diagnosis.

We know little of the life expectancy of the patients, as the Bureaus of Vital Statistics report the deaths

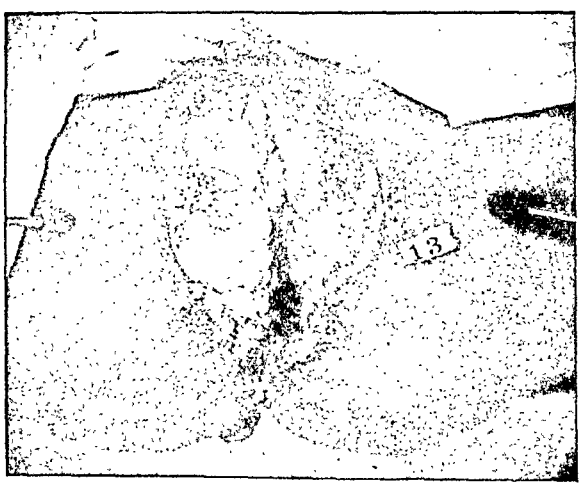

Plate No. 3

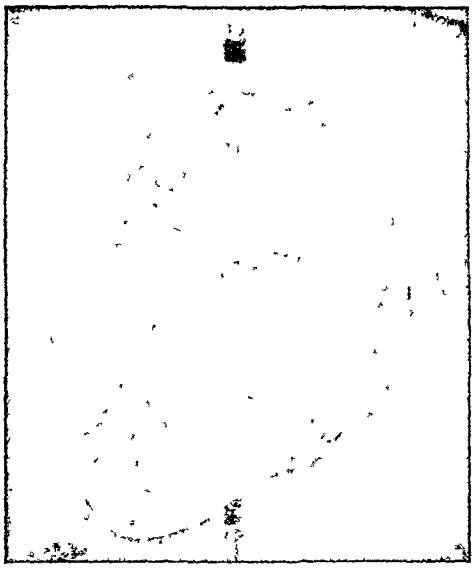

Plate No. 4

duc o everything except lymphopathia venerea. We do observe that, while we see many cases from 17 years of age and over, the number living after 50 years is comparatively small.

It would seem necessary to attend a few abbreviated histories with photographs, demonstrating the points stressed in this paper. Necessarily, much detail must be omitted.

Plate No. 1. G. W., female negress, aged 35, married twice; second marriage in 1926. Admitted to our clinic November 18, 1935. Present illness: difficult bowel movements. She says her constipation began in 1923. Operated upon that year in West Virginia for the obstruction. Operated again in Philadelphia in 1932; became progressively worse. Local examination showed elephantiasis of the vulva and esthiomene of the peri-anal tissues. Tubular rectal stricture of small calibre. Frei test plus 4, Wassermann negative. Husband examined gave Frei test plus 4. He reports a bilateral adenitis in 1927. Patient, G. W., admitted to Graduate Hospital, service of Dr. W. E. Lee, December, 1935, for preliminary colostomy. Patient decidedly anemic and rather bad cardiac condition with blood pressure 210/130. Had a preparatory blood transfusion, husband the donor, and intravenous glucose injection. Has dyspnoea on exertion and some edema of the ankles since 1929. *Operation January 6, 1936*, first stage of Lahey method for abdomeno-perineal dissection and double barrelled colostomy. Died January 15, 1936, with complicating uremia. Note: Tissue removed from perianal region and labia produced a very active antigen.

Plate No. 2. B. P., female negress, 23 years old, waitress. Massive elephantiasis of the labia, mostly on the left side, for the past two years. Frei test plus 4, Wassermann plus 4. Is being treated by the Dermantologic clinic for lues. Has been married for three years, but believes that her infection started at the early age of 13. Has beginning rectal stricture and also some inguinal scars on the left side, which she says began with an abscess five years ago. We hope to remove this tissue for purpose of producing antigens.

Plate No. 3. P. Y., female negress, 31 years old, single; service of Dr. Wm. H. Mackinney, Urology, Philadelphia General Hospital. Photographed April 30, 1936. First noticed ulceration four years ago; apparently healed after having some treatment by a private doctor. Tissue broke down again in November, 1935, and she was admitted to the Philadelphia General Hospital with a note that there was ulceration of both vulvae, and the condition was diagnosed as granuloma inguinale. Was given injections of tartar emetic and dismissed in January, 1936, apparently healed. Wassermann negative. We find on further search of history from the ward notes, that the patient had not entirely recovered, but was considered well enough for ambulant treatment. Readmitted March 23, 1936; wound broken down; ulceration involves entire recto-vaginal septum within one and a half inches of the cervix; also the perirectal tissues laterally and posteriorly. Tissue indurated. No rectal sphincter nor mucosa remain. Has incontinence and a rectal stricture of 8 or 9 caliber. She says her rectal bleeding began three and a half years ago. Clinically she has destruction of all perianal and perirectal tissue, as high as the level of the mid portion of the vagina. The ulceration includes the deep tissue of the entire perineum. She is very anemic; R.B.C. 2,310,000; hemoglobin 40%. Ulceration is so extensive that complete obstruction is not a clinical symptom. Frei test March 23, 1936, was positive subject to our's, later. Diagnosis was made of lymphopathia venerea. However, the Urologic service believes that in spite of the positive Frei test, the original diagnosis of granuloma inguinale is still valid. Note: Apparently no biopsy had been done and the chart shows no Donovan bodies have been at anytime demonstrated. Our query is, how could they be found without a biopsy? Frei test May 2, 1936, was positive with both

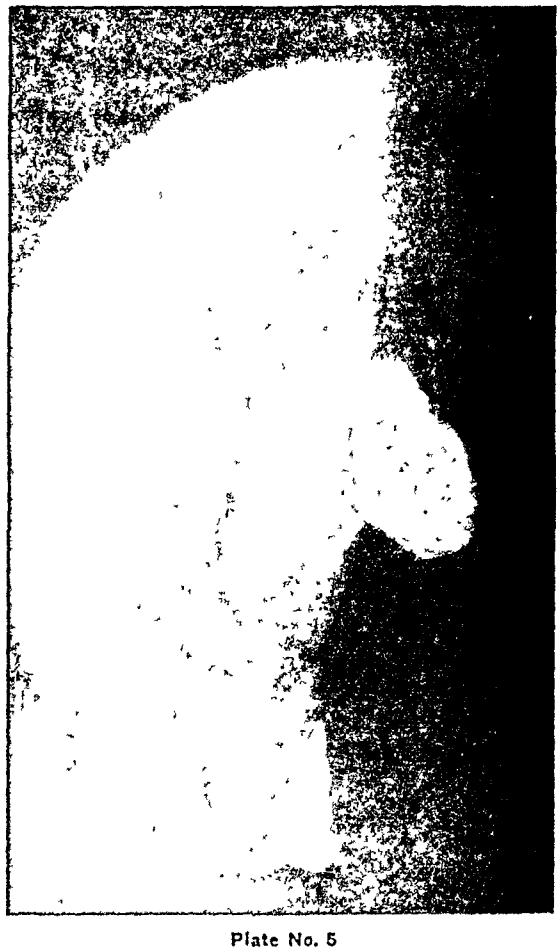

Plate No. 5

polyvalent antigen and antigen from G. W. Comment by Dr. Landreck, a student on our service: "We believe that she has lymphopathia venerea. If a biopsy is done and Donovan bodies can be demonstrated, we think that this is a case of double infection, namely lymphopathia venerea and granuloma inguinale."

Plate No. 4. W. J., colored male, 36 years old, single, lived in Philadelphia since birth. Admitted to Philadelphia General Hospital, service of Dr. Wm. H. Mackinney, three years ago, with granuloma inguinale, and apparently has received continuous treatment from that time. Has gained 137 pounds since admission. Lesion consists of bilateral adenitis, edema and elephantiasis of the penis, scrotum and perineum. *Apparently acquired infection in 1925.* While in the hospital condition healed and broke down several times. He reports that his inguinal glands were removed 15 years ago, which would bring the date of the primary infection to 1921. At the present time has edema and elephantiasis of the shaft of the penis and a general elephantiasis and fibrosis of the scrotum. Frei test is positive and we feel sure that this is a case of lymphopathia venerea and probably not granuloma inguinale as no Donovan bodies have been reported.

Plate No. 5. W. J., colored male, 40 years old, single, from Urologic Clinic, Philadelphia General Hospital, Dr. Wm. H. Mackinney. Case demonstrated as one of granuloma inguinale of the penis. Infection acquired in 1932 in Baton Rouge, La.; came to Philadelphia General Hospital fourteen months ago; diameter of shaft of penis at that time, four and one-half inches. Wassermann 4 plus. Frei test at that time, negative. Biopsy showed no Donovan bodies. Patient received injections of salvarsan and mixed treatment until Wassermann became negative. Some improvement after receiving tartar emetic injections and X-ray irradiation. Frei test positive April 11, 1936, and also April 13; antigens used polyvalent No. 2 and Vann. Reports from pathologic laboratory March 12, 1935, "acute phlegmanous cellulitis of penis" and April 9, 1936, "chronic hyperplastic lymphadenitis." In spite of the fact that no specific picture was shown upon examination of the tissue, we feel that this should not be expected in the chronic type of lesion; the acute bubo probably giving us the best picture. With the positive Frei reaction, the fibrosis and elephantiasis of the shaft of the penis, and elephantiasis and edema of the scrotum, would make us feel that this is surely a case of lymphopathia venerea.

SUMMARY

In summing up, we simply call attention to the immense variety of gross lesions encountered and the difficulty of diagnosis. The confusion between granuloma inguinale and lymphogranuloma inguinale, or lymphopathia venerea is possibly due to the fact that many of these cases of lymphopathia venerea do improve somewhat under injections of tartar emetic. That leaves us with only two points for a differential diagnosis: first, the presence of Donovan bodies in tissues removed, and second, the presence or absence of a reaction to the Frei antigen. We believe that the antigen is specific. We also believe the Donovan bodies to be diagnostic; therefore, should we find both, the patient must have two diseases.

SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

MEDICAL Classics. Williams and Wilkins, Baltimore, Md., Vol. No. 1, September, 1936. Edited by Emerson C. Kelly, M.D., Albany Medical College, Medical Classics, while being published monthly, is not so much a journal as a series of small books, each more or less complete in itself. The first issue presents three of Sir James Paget's most important contributions to medicine, all printed exactly as written, with facsimile reproductions of the title pages of each article. Much biographical material concerning Paget is included. A preface states the nature of the publication and gives a forecast of subjects to be treated in early ensuing issues.

The format and printing are very attractive and live up to the traditions of the publishers. The material is extremely interesting to those who have a liking for historical fact. It is predicted by the reviewer that Medical Classics will meet with encouraging success.

Beaumont S. Cornell, Fort Wayne.

Physician, Pastor and Patient, by Geo. W. Jacoby, M. D., with an Introduction by Harlow Brooks, M.D. Published by Emerson Books, Inc., New York, June, 1936, 252 pages. Price $2.00.

THE author of this book, a past president of the American Neurological Association, has attempted to bridge the apparent gap between medical science and religion, and to establish a sound basis upon which the physician and the pastor may join their efforts for the betterment of the individual, not only as a patient but also as a member of the community. Hence he devotes several chapters to a somewhat brief, but for the purpose, satisfactory outline of the development of medical science and similarily, to the origins and development of the religious beliefs held by the various peoples of the world. Particular emphasis is laid on the changes that have occurred in personal hygiene and measures of health and type of medical practice in the centuries of progress which witnessed the breaking of the fetters of religious intolerance and led to the emancipation of the individual. Having thus established a common ground, the author discusses the major problems which confront both the physician and the pastor in his relation to the community. He is quite modern in his liberal attitude towards contraception, artificial abortion and birth control, and quotes freely from medical and religious sources, to maintain his point against the ironclad laws which obtain in Catholic regulations.

There are interesting chapters on the problems of suicide and insanity, divorce, criminality, sterilization, sex education, the mentally sick, euthanasia, vivisection and its role in the development of medicine and secrecy in medical ethics. Throughout he would

like to establish more friendly and cooperative relations between the physician and the pastor.

Although the book is somewhat choppy in spots, because of attempts to cover too much ground in the allotted space, it is fairly well written and should be of greater informative value to the layman than the physician.

Leon Bloch, Chicago.

Food, Fitness and Figure, by Dr. Jacob Buckstein.

THIS small but concise and well written volume comes at an opportune time. Much is being written about the question of weight reduction, mostly by individuals who have had no scientific training and whose advice is often not only worthless but actually harmful. In this very interesting volume Dr. Jacob Buckstein, a worthy authority, has incorporated not only worthwhile advice about foods and reducing diets but also diets for gaining weight. The entire subject of foods, vitamins, minerals, food values and the necessary amounts of food for healthy living is explained in scientific yet simple language for lay consumption.

There are many interesting chapters on the discovery and development of meats—vegetables—milk—fruits—nuts and beverages. Simple, yet convincing and scientific suggestions are made about such debatable subjects as coffee, tea, alcoholics, vegetarianism and fasting. The last one-third of the book consists of itemized diets for gaining and losing weight—food values—protein and vitamin contents of specific foods and specific amounts.

In short, here is a volume of information that can be recommended by a physician to his patient which not only needs no apology but which represents the best sound and scientific knowledge on the question of foods and weight reduction.

SECTION XII—"*The Clinic*"

Primary Leiomyosarcoma of the Upper Third of the Esophagus*

By

FRANK R. MENNE, M.D., F.A.C.P.†

and

RICHARD F. BIRGE, M.D.

PORTLAND, OREGON

THAT true leiomyosarcomas are rare is attested by the fact that Kraufkopf (1) in 1933 was able to find only thirty-one recorded cases in the literature. One of the least common sites of these tumors is the esophagus, and a case of leiomyosarcoma of the upper one-third of the esophagus, where the musculature is predominantly of the striate variety, has apparently never been recorded. Oddly enough, in two of the three reported cases of rhabdomyosarcoma of the esophagus, the new-growth occurred in the lower portion of the esophagus (Wolfensberger (2) and Glinski (3)). Dvorak (4) described the only case of rhabdomyosarcoma of the cervical portion of the esophagus.

The earliest case of primary leiomyocarsoma of the esophagus is that of Howard (5) who, in 1902, described the occurrence of a diffuse infiltrating mass in the distal twelve centimeters of the esophagus. There were associated ulceration of the esophageal mucosa and metastases to the stomach and regional lymph nodes. The new growth was a mixed cell sarcoma apparently divided wholly from the smooth muscle tissue of the esophagus, and Howard states that all graduations of cell types, from normal smooth muscle cells to the large tumor cells, could be traced. Von Hacker (6) reports Eppinger's case of leiomyosarcoma of the esophagus, stating that the tumor occurred as a polypoid mass filling the widely dilated lumen of the lower end of the esophagus. The tumor was composed of large, spindle-shaped cells with interspersing bands of white, homogeneous smooth muscle. There were no metastases. Recently a third case of leiomyosarcoma of the esophagus associated with a diaphragmatic hernia has been described in the Case Records of the Massachusetts General Hospital (7). Mallory says the tumor mass was found in the terminal portion of the esophagus, stopping absolutely short at the cardia. There was metastasis to a group of mediastinal lymph nodes on the anterior surface of the esophagus just behind the pericardium. The histological description of the tumor is not given. In view of the fact that leiomyosarcoma of the upper one-third of the esophagus is extremely rare, it seems justifiable to present the following case.

CASE REPORT

A white painter, aged 38, was admitted to the hospital on January 18, 1936, complaining of inability to swallow

*From the Pathological Laboratory of the Veterans Facility and the Department of Pathology of the University of Oregon Medical School.

†Professor of Pathology, University of Oregon Medical School; Consultant Pathologist to the Veterans Facility, Portland, Oregon.

‡Received September 23, 1936.

Fig. 1. Autopsy No. 28-4-36. Photograph No. 1. Reproduction of the X-ray showing the peculiar distribution of the barium in the esophagus.

solid food and loss of eighteen pounds in weight in the past year. He stated that in 1929 he had first noticed a soreness in the right side of his throat, associated with some pain on swallowing and with a bad odor coming from the mouth. He added that in the past year there was increased difficulty in swallowing and that for two months he had been unable to swallow anything but liquids. For some time he had been unable to clear his throat and had expectorated small amounts of dark brown material, but there had been no regurgitation of food or blood. The past history, except as related to the present complaints, was unessential.

The patient had been seen early in 1935 by Dr. T. M. Joyce of Portland, Oregon, when *Radiographic studies* of the esophagus showed it to be dilated above the level of the second dorsal vertebra and the patient was noted to have difficulty in swallowing barium. An *esophagoscopic examination* was therefore done and a biopsy made. Definite malignancy, either an anaplastic carcinoma or possibly a sarcoma, was reported by the pathologist. A few days later the esophagus was exposed through the neck and 30 mg. of radium were implanted in the tumor wall and allowed to remain for ten hours. There was improvement for some time, and the patient had less difficulty in swallowing. The patient was also stated to have been given X-ray treatments by another physician in June, 1935.

Physical examination revealed a white male weighing 120 pounds. In the neck there was a sausage-shaped swelling beginning just below the larynx and extending beneath the sternum. This mass was firm, hard but not tender. On the skin surface to the right of the midline the healed incision of the previous radium implantation was seen. There were no other essential findings on physical examination. *Laboratory studies* showed the urine and blood to be negative. The white count ranged from 9,000 to 11,600, and the neutrophilic forms ranged from 85% to 90%. During his stay in the hospital the patient's temperature ranged from 36.0 to 37.6. *Radioscopic and radiographic studies* of the esophagus on January 23, 1936, showed the barium to spread out in an unusual manner, irregularly filling the upper portion of the esophagus. A narrowing of the lumen was observed at the level of the sixth cervical vertebra, not sufficient, however, to prevent the rapid passage of the barium to the level of the aortic arch where another narrowing was seen. Between the two constrictions a considerable degree of widening of the esophagus was observed. Below the arch, the barium proceded rapidly to the cardiac orifice where there was evidence of slight spasm which quickly relaxed, permitting fairly rapid passage of the barium into the stomach. (See radiographic reproduction No. 1. Dr. Bloom, V. F., Portland, Oregon).

Because of rapid recurrence after previous high voltage therapy, irradiation of the tumor mass was not considered at the time of entrance. A gastrostomy was done (Dr. Peiffer, G.) on March 9 for the purpose of conserving the patient's strength and for palliation. Following the gastrostomy the neck was cautiously irradiated, small dosage being employed to prevent edema of the glottis. On March 18 the patient complained of pain in the neck, which was swollen, red and indurated on the right side.

Fig. 2. Autopsy No. 28-4-36. Photograph No. 2 illustrating the massive fungoid growth which occupied the upper end of the esophagus, projecting upward into the pharynx. Note the base of the tongue at the top of the photograph at "T"; the hemorrhagic, necrotic mass at "H."

Fig. 3. Autopsy No. 28-4-36. Photograph No 3 of a sagittal section made through the tumor mass. "T" tongue; "E" probable area of origin of the tumor with extension forward into the trachea; "H" hemorrhagic mass projecting downward in the esophagus.

Several days later an abscess of the neck was opened and drained. Following this flare-up the dysphagia gradually increased. On April 19 there was considerable bleeding from the throat, and the patient expired two days later.

At the autopsy (F.R.M.) the body was seen to be that of an emaciated white male. The neck was asymmetrical with the presence of a roughly nodular swelling on the right side, lateral and inferior to an old healed scar extending from the sternal notch upward along the anterior *border of the right sternocleidomastoid* muscle. The left side of the neck showed some rather diffuse swelling but no other abnormality. The gastrostomy wound was found to be normally functional. When the neck was opened a mass of extremely friable, bloody, necrotic tissue, in which were large nubbins of whitish tissue, was found in the posterior pharynx. (See photograph No. 2). This mass was continuous with a larger mass completely occluding *the laryngopharynx and esophageal lumen*. Examination of the mass revealed it to consist of a whitish, firm, papillomatous growth attached to the anterior wall of the pharynx and to the right lateral wall of the esophagus in its first 10 cm. (See photograph No. 3).

There was a good deal of hemorrhagic necrosis in this tissue, and an extension of the hemorrhagic necrotic tissue was seen to almost occlude the laryngeal opening. A portion of the growth had also invaded the right side of the epiglottis. In the neck below the lower end of the right sternocleidomastoid muscle the abscess cavity mentioned in the clinical history was found to communicate with the superior end of the esophagus at a point 7.0 cm. inferior to the uvula. The palpable nodule in the neck was found to surround the hemorrhagic abscess cavity and to be composed in part of thyroid tissue. The base of the tongue was uninvolved. There was edema of the glottis with partial closure, although a small lumen measuring 3 mm. in diameter was seen. There was no direct compression of the trachea by the neoplasm. Beneath the pleural surfaces of the lungs were found whitish, hard, *discrete nodules* averaging 3 mm. in diameter and a few somewhat larger nodules were found deeper in the parenchyma of the lungs. There were no other evident metastases.

Microscopic sections taken from various areas of the fungoid tumor mass projecting into the lumen and invading the wall of the esophagus revealed more or less compact areas of cells having spindle-shaped or oval nuclei. The cells had in general a dense, longitudinal arrangement. The nuclei were quite long but relatively narrow and possessed rounded ends. They tended to stain uniformly slightly black, and were granular. The nucleoli were not prominent. The cell boundaries were not well defined, but the staining reaction of the cytoplasm was pinkish. Mitotic figures were infrequent. The tissue in general was richly vascular and there were many areas of hemorrhage throughout it. In certain portions of the tumor there was evidence of dissociation of blood pigments which were found both intra- and extra-cellularly. In the grossly hemorrhagic area there was a recent thrombus formation, apparently occurring in a large sinusoidal vessel. In certain areas the nuclei were widely separated and here there was infiltration of leukocytes, serum and fibrin in abundance. In other areas there was myxomatous degeneration. In the more superficial portions of the tumor there were necroses with heavy depositions of fibrin and secondary invasion of polymorphonuclear leukocytes. However, the stratified squamous epithelium was intact over portions of the tumor except where the invasion of polymorphonuclear cells occurred. In some areas there was also superficial granulation tissue formation projecting beneath the epithelium, which was greatly thinned or eroded. There was no evidence of epithelial cell proliferation. The elongated oval to spindle-shaped tumor cells of one of the *metastatic nodules in the lungs* were similar in appearance to those in the primary tumor. The nucleoplasm was also granular and finely stippled. There were no prominent nucleoli and mitotic figures were not seen. The nodule, which obliterated the atrial openings, was surrounded by histiocytes, monocytes and plasma cells. (See photomicrograph No. 1). The application of differential stains (van Gieson) revealed the predominant cell to be of the nonstriated muscle type.

COMMENT

Clinically, there were some unusual features in this case because of the unusually high position of the tumor mass. Thus there was associated abscess formation in the neck with development of a sinus tract extending from the esophagus through the abscess cavity to the surface through the operative incision. Yet the patient died as the result of hemorrhage from a vascular tumor mass with asphyxia due to aspiration of blood. Such cases as this can only be differentiated from the more common carcinomas of the esophagus by microscopic examination of the tumor tissue, provided representative tissue is secured. The chief symptom in both types of malignancy of the esophagus is dysphagia, and other symptoms are related largely to the obstruction. Although the course of sarcoma of the esophagus is said to be more rapidly fatal than carcinoma, the patient's symptoms began with pain on swallowing, six years before death occur-

Fig. 4. Autopsy No. 28-4-36. Photomicrograph No. 1 of a metastatic nodule in the lung disclosing the characteristic cell type as seen in the original tumor.

red. The early occurrence of pain on swallowing in this case of course suggests the possibility of early diagnosis and possible successful management of a relatively accessible neoplasm of the cervical portion of the esophagus, had the patient been seen in 1929. If there are any characteristics of sarcoma of the esophagus which differentiate it clinically from carcinoma, they are pain and the prominence of signs and symptoms that develop in such malignancies of the cervical portion of the esophagus. The only ray of hope in these cases, as in malignancy generally, is the recognition of the significance of early symptoms and the prompt attempt at treatment, for Von Eicken (8) believes the slow growing spindle cell sarcomas to be operable lesions, and the occasional benign tumors causing symptoms may also be removed.

It need hardly be mentioned that the muscular tissue of the esophagus varies in different parts of the tube. Within approximately the lower half of the esophagus the muscle is entirely unstriated, within the second quarter both striated and smooth muscle appear, while in the first quarter striated muscle almost exclusively is present. The zone of purely striated fibers is said to extend somewhat further in the longitudinal than in the circular layer, but the zone of purely striated fibers within the latter includes only about the first 2.5 cm.

It is therefore not necessary to postulate embryonic rests in the upper esophagus to account for the origin of the tumor we have described. Nevertheless it is possible, as Dvorak (4) believes of the rhabdomyosarcomas of the esophagus, that the smooth muscle sarcomas may arise from undifferentiated mesenchyme displaced when the marked developmental changes occur in the ventral floor of the embryonic foregut.

SUMMARY

The leiomyosarcoma here reported evidently grew slowly and invaded slowly. Its extension into the trachea anteriorly probably resulted in the implantation metastases in the lungs since these secondary growths were found in the vicinity of terminal bronchi. It was spontaneous hemorrhage from portions of the vascular tumor, the blood welling up about the epiglottis and being inhaled, that caused death in this case of an unusual neoplasm in the upper portion of the esophagus.

Hodgkin's Disease of the Pel-Epstein Type

By

RALPH W. MENDELSON, M.D.

and

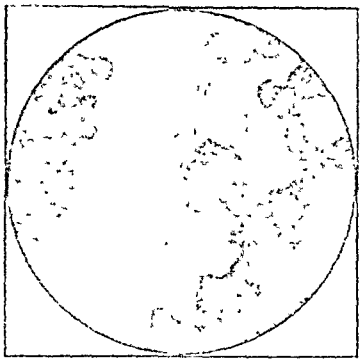
E. E. ROYER, M.D.

ALBUQUERQUE, NEW MEXICO

A CONSIDERABLE literature has accumulated with regard to Hodgkin's disease, but the etiological factor still remains unknown. It would be academic to enter into a discussion regarding the various theories advanced nor have we anything new to offer in the line of pathology.

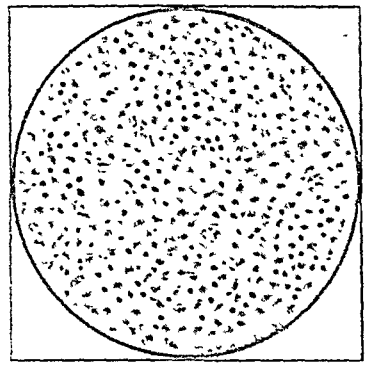
Our patient is of interest from a diagnostic viewpoint for the reason that it so beautifully illustrates the Pel-Epstein type of the disease. This type first was reported by Murchison in 1870 and more carefully studied by Pel-Epstein and later by MacNalty, who states:

"Following on a period of low pyrexia, or of normal or subnormal temperature, there is a steady rise occupying two or four days to a maximum, which may reach 105°. For about three days the temperature remains at a high level, and then there is a gradual fall by lysis occupying about three days, and the temperature then becomes normal."



This course usually is followed by an afebrile period of from a few days to one or more weeks when another bout of fever manifests itself. This peculiar type of temperature cycle may be the only manifestation of the disease or may be present with either general or local lymphatic enlargement, such as the cervical, thoracic or retroperitoneal chain. The case here presented is of the latter type, the history being as follows.

CASE HISTORY



The patient was a white male, age 42, a salesman. His father died at the advanced age of 83 and his mother is living at the age of 72, and affected with the usual disabilities of advancing years. There are four living brothers who are in good health. There are no sisters.

The *past history* includes the usual diseases of child-

Submitted October 11, 1936.

Hodgkin's Disease spleen — Low power.

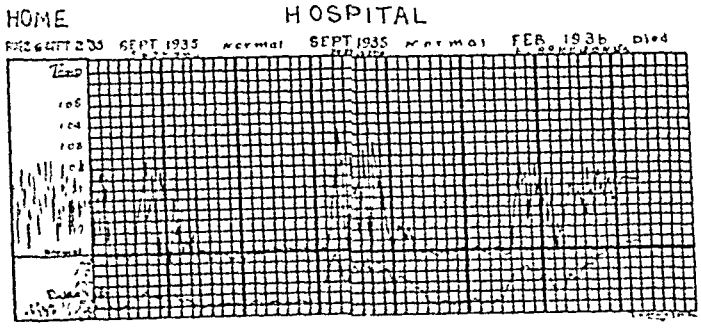
High power section from retroperitoneal glands showing a few cosinophiles, lymphoid, epithelioid and large multinuclear cells. Hodgkin's Disease.

hood, typhoid fever as a youth, tonsilectomy some few years ago and pulmonary tuberculosis (?) diagnosed ten years ago, but arrested for the past six years.

The *present condition* first manifested itself in the early part of August, 1935, when the patient developed a relapsing type of fever, accompanied by chills and free perspiration. The temperature varied, daily, from normal to 102°. There were no other signs or symptoms of disease and but for the discomfort and weakness incident to the continued abnormal temperature, the patient had no complaints. This state of affairs continued until September 2; then for three days the temperature remained normal, but on September 5 the pyrexia returned and the patient entered the hospital for observation.

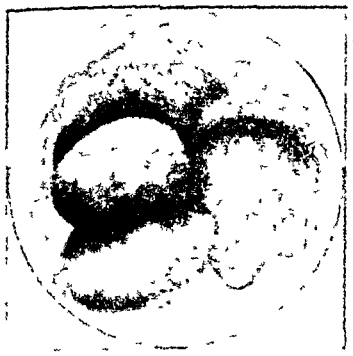
The *examination* revealed a man weighing 125 pounds, 5 feet, eight inches in height. The head (including the ears, nose, throat and mouth was negative. The teeth were in good condition. The tonsils were absent. The lungs were normal on physical examination and the X-ray report stated that there was no evidence of recent, or anything to indicate, active trouble. The cardio-vascular and the genito-urinary and neuro-muscular were normal. The skin was without defect. The urine was essentially negative except for a trace of albumen. The white blood-cell count was normal and the differential count was without interest. There were no eosinophiles. Agglutination tests for typhoid, para-typhoid "A" and "B" and abortus-melitensis all were negative in all dilutions.

Symptomatic *treatment* was instituted and the temperature declined to normal on September 11. The patient insisted on returning home on that day where he remained quite well until September 23. Then he experienced a severe chill followed by an acute elevation of temperature. He returned to the hospital and again all laboratory findings were negative. Malaria and relapsing fever were ruled out by careful blood studies. The patient complained of no discomfort except such incident to a sudden rise in temperature. There were no positive physical findings.



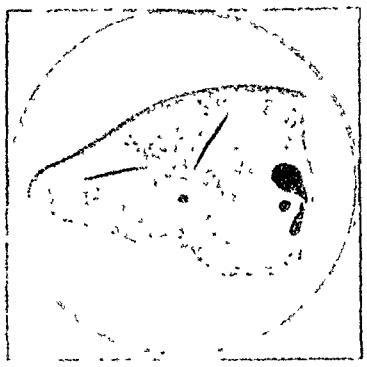
Stool examinations at this time were negative and sigmoidoscopic examination revealed a normal bowel, so far as could be observed. Wassermann negative.

In view of the complete absence of all physical and laboratory findings and the suggestive type of temperature we made a presumptive diagnosis of Hodgkin's disease of the Pel-Epstein type and requested an X-ray examination of the lumbar and pelvic areas in order to visualize, if possible, any glandular enlargement. The report stated that a film taken of the lumbar and pelvic areas, with soft technique with the idea of showing up soft structure in the abdomen in more detail, showed no evidence of pathology.



Gastro-intestinal examination was normal except for an unusual spotting throughout the colon, which assumed the form of linear petechia, best seen through the cecum and ascending and transverse colons. The descending colon was well distended and showed normal markings, but also considerable linear petechial spotting. This petechial spotting was reported as indicating an inflamatory condition of the colon, but such roentgen observation was not in accord with the stool and sigmoidoscopic examinations, nor did the patient at any time have symptoms of colonic inflammation.

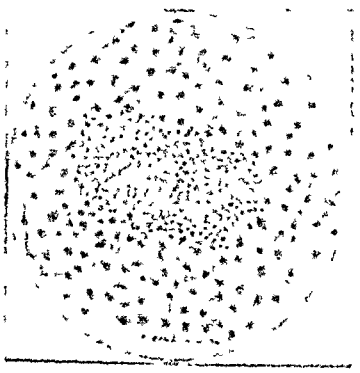
Careful examination for signs of external glandular involvement was negative; there was no material for a Gordon's test.



As *treatment*, we exhibited Fowler's solution and by September 28, the temperature was normal and the patient again insisted on returning home. He continued his treat-

Temperature Chart, Hodgkin's Disease. Pel-Epstein type.

Enlarged retroperitoneal glands in Hodgkin's Disease.



Miliary Hodgkin's of liver.

ment for a short time only. His condition improved noticeably. He was up and around and entered actively into the New Year's festivities. He remained free from any disability until February 6, 1926, when he again experienced a severe chill followed by an elevation of temperature of 105°. He returned to the hospital complaining of intense frontal headache *and was distinctly jaundiced.* The area of liver dullness was distinctly increased, but to what exact extent could not be determined on account of marked abdominal distension. The spleen could not be palpated although the abdominal tympanites did not obliterate dullness in that area. The external glands were not enlarged. The *jaundice gradually increased,* the high temperature with chills and sweats continued and the patient expired February 16, 1926.

Two days previous to death, a single gland appeared in the left inguinal region enlarged to the size of an almond. An *autopsy* was requested and permission granted. The report of Dr. J. R. Van Atta, pathologist, follows:

"The body is that of an adult male about 41 years old, 5 feet, six inches in height; weight about 140 pounds, fairly well developed, but poorly nourished. There is deep general icterus. There are no operative scars. The thorax was opened with the usual incision. Both lungs show the apical adhesions of an old tuberculosis; there are some caseous tuberculous nodules in the apex on the left side. The remainder of the pulmonary area appears normal. The heart and great vessels were not disturbed. No mediastinal glands were noted.

Section from liver — High power Hodgkin's Disease

When the abdomen was opened the liver exhibited a peculiar mottled appearance suggestive of widespread miliary, fatty or amyloid degeneration. The liver was greatly enlarged. The spleen was about twice normal size and showed the same infiltrative process as the liver. The gall bladder was pale and contained mucus. The ducts were all patent. The gastro-intestinal tract was normal grossly throughout. The pancreas appeared to be enlarged. The kidneys appeared normal.

The main pathology in the abdomen consisted of a chain of retro-peritoneal glands which were greatly enlarged, some being hen-egg in size. There were several of these which were matted together with loose fibrous tissue, but the glands themselves were quite discrete. A single almond sized gland was found in the left groin and removed. Section of the retro-peritoneal glands and the inguinal gland show a Hodgkin's disease. The infiltrative spots in the liver consisted of deposits of the typical tissue of Hodgkin's; the same was true of the spleen except the spleen showed considerable secondary infection; the pancreas appeared normal except for some round cell infiltration. The adrenal was normal."

This patient beautifully illustrates a typical case of Hodgkin's disease of the Pel-Epstein type. We do not feel that the old pulmonary tuberculosis in any way affected the picture. We do feel that the presumptive diagnosis was justified in view of the complete lack of laboratory and physical findings in the presence of the characteristic type of temperature curve. At no time during the course of the disease were there any unusual pulmonary, gastro-intestinal, cardio-vascular, genito-urinary, neuro-muscular or other signs or symptoms that might not obtain as the result of attacks of high temperature. The terminal jaundice is accounted for by extensive terminal hepatic involvement; this is not a common finding. The patient made considerable recovery after each period of illness. He suffered no pruritis at any time during the course of his disease.

The illustrations accompanying this report are self explanatory. Special attention is directed toward the liver sections, as they exhibit pathology not common in Hodgkin's disease.

Myelophthisic Anemia in a Case of Carcinoma of the Stomach. J. A. M. A., Vol. 107, pp. 963-964, Sept. 19, 1936.

The usual picture of anemia in carcinoma of the stomach is of the secondary type, due to chronic blood loss. In cases in which there is a concomitant achylia gastrica there frequently is a disturbance in hematopoiesis resulting in an anemia of the pernicious type.

A third type of anemia engages our attention at present—a so-called myelophthisic anemia, hemolytic in nature and occurring in diseases which destroy bone marrow. Metastatic carcinoma especially from the breast, thyroid, prostate or stomach is an occasional cause of this type of anemia. It is characterized by a diminution in the red blood cells, low hemoglobin content, marked anesocytosis and poikilocytosis, and a high percentage of polychromatophilic cells and nucleated forms. Myelocytes are frequently found in the circulating blood. Waugh claims that there is an increased fragility of the red cells. Pepper and Forley also say that in the terminal stages there is a complete oplasia of the bone marrow.

The author reports a case treated originally for influenza and tuberculosis which at autopsy revealed an adeno-carcinoma of the stomach with widespread metastasis involving the bone marrow. The blood picture was typical of that described above, except that the fragility of the red cells was normal.

Francis D. Murphy, Milwaukee.

GOLDMAN, LEON

"Gross Hemorrhage from Peptic Ulcer — Its Morbility, Mortality and Treatment." J. A. M. A., 107:1537-1541, Nov. 7, 1936.

This study is based upon a series of 1,025 admissions of 890 patients with peptic ulcer and it includes a seven year period in a charity hospital. The rather irresponsible class of patients affected may account in part for the high incidence and mortality observed in regard to gross hemorrhage, but will probably have little bearing upon the other observations noted.

Gross hemorrhage was the presenting symptom or a development in complication in 38 per cent of the cases and of this group 11.1 per cent died of exsanguination and an additional 4.9 per cent of conditions associated with the bleeding—in other words 16 per cent of those patients having gross hemorrhage died. Fatal hemorrhage usually is caused by erosion of a large artery along the posterior wall of the first or second portion of the duodenum where it overlies the pancreas. This is explained by the fact that these ulcers are less likely to heal than those elsewhere and that with the desruction of the duodenal wall the vessel is surrounded by granulation or scar tissue which has a tendency to hold the artery open and render its walls less elastic.

Exacerbation or recurrence of the symptoms of ulcer usually immediately precedes the onset of hemorrhage. Dietary indiscretion or alcoholic indulgence may have occurred. Nausea is the first system and may be followed by the vomiting of blood and by fainting. Tarry stools occur later but either tarry stools or hematamesis may occur alone, or both may occur, whether the ulcer is in the stomach or duodenum. Shock follows severe hemorrhage and until the fluid volume is replaced blood pressure readings are more accurate than blood counts in estimating the severity of the hemorrhage.

While the rule is quite variable, tarry stools occur more often and hematemesis less often in duodenal ulcers. The incidence of gross hemorrhage reached its peak during the fifth decade, and the mortality was highest in the fifth, sixth and seventh decades when arteriosclerosis is important. In all fatal cases the hemoglobin was below 30 per cent and the red count less than 2 million. The mortality rate showed a definite abrupt rise after the second hemorrhage, and recurrence of hemorrhage is more likely after two have occurred than after the initial hemorrhage.

Treatment consists of absolute mental, physical, and intestinal rest. The patient should be put to bed and given enough morphine to accomplish this. Atropine should be given with the first few doses of morphine to relax the muscularis and inhibit gastric secretion. Blood pressure reading and frequent red counts and hemoglobin determinations should be made. Nothing is given by mouth except alkaline powders. After bleeding has stopped the Sippy regimen can be instituted. During the first 24 or 48 hours parenteral fluids are withheld. Nothing is given intravenously except blood which probably aids in checking hemorrhage far more often than it starts bleeding again. Transfusion is indicated when the systolic pressure is less than 70 mm., the hemoglobin less than 40 per cent, or the patient's general condition such that a second hemorrhage would probably be fatal. Other coagulants or astringents are ineffective. Gastric lavage should be employed only when the stomach is distended with clots. Early surgery is indicated in those patients who continue to bleed or have repeated hemorrhage under adequate medical treatment as described. This is especially true of those in the arteriosclerotic age.

J. Duffy Hancock, Louisville.

SNELL, ALBERT M.

The Effects of Calculous Biliary Obstruction on the Structure and Functions of the Liver. S. G. O., 63:596-603, Nov., 1936.

Accurate estimation of the degree of hepatic pathological and physiological change is not always possible even when the duration and relative completeness of the biliary obstruction present in any particular case is known. This is explained by a number of variable factors: the stones may remain latent, doing damage but not causing symptoms; in different individuals there will be a difference of degree in response of liver tissue to injury; and there is some inconstancy in the interpretation of tests of liver damage.

The pathological lesions following jaundice and common duct obstruction fall into four groups. In the first group which embraces about two-thirds of all the cases, there is a minimal structural change and only slight disturbance of liver function. The cases present only simple uncomplicated biliary obstruction, there is a relatively short history of biliary colic, the jaundice is slight and transient the biliary passages are patent, and the serum bilirubin determination averages about 3 mg. per 100 c.c.

In the second group severe ascending biliary infection plays a major part in the destruction of the hepatic parenchyma, there is a febrile course, the jaundice is deeper and more persistent, intermittent obstruction is quite characteristic, the serum bilirubin varies from 8 to 15, hemorrhagic features and rental insufficiency are common, and there is a frequent associated pancreatitis.

The third group shows an acute or subacute atrophy and degeneration of the liver, an extreme degree of jaundice persists even after the biliary colic subsides and there is increased potency of the biliary passages, the serum bilirubin varies from 15 to 20 mgm., the hemorrhagic tendency is

CONSERVATION OF ESSENTIAL ELEMENTS IN PROTECTIVE FOODS

I. MINERALS

● Considerable differences may exist between the mineral contents of foods from both the qualitative and quantitative standpoints. In fact, variation in mineral content has been noted even in the same plant variety; such variations being dependent, among other factors, upon soil or climatic conditions (1).

A striking example of the influence of one of these factors is the relative richness in iodine of field crops raised in certain coastal regions of this country where the soil is also high in iodine.

From the point of view of those concerned with human nutrition, interest in the mineral content of the food supply is usually centered around calcium, iron and iodine; since it is generally agreed that of all the essential minerals, these are the ones most apt to be inadequately supplied by the average varied diet. Conservation of these minerals in foods is, therefore, a matter of considerable practical interest.

Unlike the vitamins, minerals are not lost during storage of fruits and vegetables. However, solution losses during cooking may be severe, due to the fact that most minerals, as they occur in the plant, are soluble, or at least are extractable, by the water in which they are cooked. For example, cabbage cooked by the usual home method has been shown to lose from 21 to 72 per cent of its calcium (2).

As exemplified by these studies, solution losses of minerals in leafy vegetables are usually high. Losses in vegetables as a class are not, however, so excessive, as indicated by an average reported loss of 19.5 per cent of the calcium in seven common vegetables (3).

The average decrease during cooking in the ash content of five common vegetables has been found to approximate 37 per cent (4).

While the extent of mineral loss during ordinary home cooking methods will vary with the particular element under consideration as well as the food in which it is contained, sufficient evidence is at hand to indicate that such losses may be considerable. It is further apparent that discarding the cooking water—the usual home practice—entails a loss of valuable, essential mineral components of food.

Modern practice in commercial canning goes far in preventing these solution losses of minerals. Canned foods are cooked by the heat process accorded them while still contained within the hermetically sealed can. A minimum of water is used which also remains within the can, conserving for the consumer's use those extractable essential mineral elements which may be lost to the cooking water during home preparation of market varieties of foods.

AMERICAN CAN COMPANY

(4) 1917 Amer J Dis Child, 14, 34

This is the twentieth in a series of monthly articles, which will summarize, for your convenience, the conclusions about canned foods which authorities in nutritional research have reached. We want to make this series valuable to you, and so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

marked, and hepatic insufficiency is apparent.

The fourth group is characterized by either advanced hepatitis with beginning fibrosis or by the development of actual cirrhosis. They develop in individuals having intermittent and incomplete obstruction over a long period of time, the jaundice is slight and constant, the liver and spleen firm and enlarged, but hepatic insufficiency and cholemic bleeding not so common as might be expected. These four groups are not so clear-cut as described and combination forms are often present.

In the latter three groups where there is more or less serious liver damage the metabolic functions as a rule are not greatly disturbed. Estimation of damage must therefore be based upon other functions; the excretory, the detoxifying, and the manufacturing function. Diminished excretion is evidenced by high readings for serum bilirubin and increased urobilinogen in the urine. The detoxifying function is tested by the amount of elimination (in the urine) of hippuric acid following the ingestion of sodium benzoate. An elimination of less than 50 per cent is significant provided renal function is apparently normal. The manufacturing function is concerned with the formation of the blood proteins, fibrinogen, hemoglobin, serum albumin, and serum globulin. Fibrinogen is usually disregarded since it is subject to so many other factors.

None of the hepatic functional tests accurately foretell the tendency to cholemic bleeding. Nygaard's method of determining the plasma coagulability is probably the best test for this.

An interesting tabulation is included.

J. Duffy Hancock, Louisville.

Soricin-Merrell

● Dorst and Morris, Burger and other clinicians have demonstrated the fact that toxic absorption from the intestinal tract may be decreased by the oral administration of Soricin.

When given in adequate amounts over a reasonable period of time, Soricin (capsules or tablets) relieves the many conditions that accompany or result from intestinal toxemia.

Soricin is non-toxic and is not absorbed from the bowel. Large doses have been given over long periods of time without any ill effect.

DOSAGE FORMS: Soricin Capsules—Enteric capsules of sodium ricinoleate available in five-grain and ten-grain sizes. • Soricin Tablets—Enteric coated tablets each containing five grains of sodium ricinoleate.

ACTION: Detoxifies in vivo • Desensitizes • Inhibits putrefaction • Prevents toxic absorption.

INDICATIONS: Bacterial Hypersensitivity of the intestinal tract • Intestinal toxemia • Intestinal allergy • Allergic diarrhea • Urticaria • Angioneurotic edema • Colitis.

Literature and Sample on Request

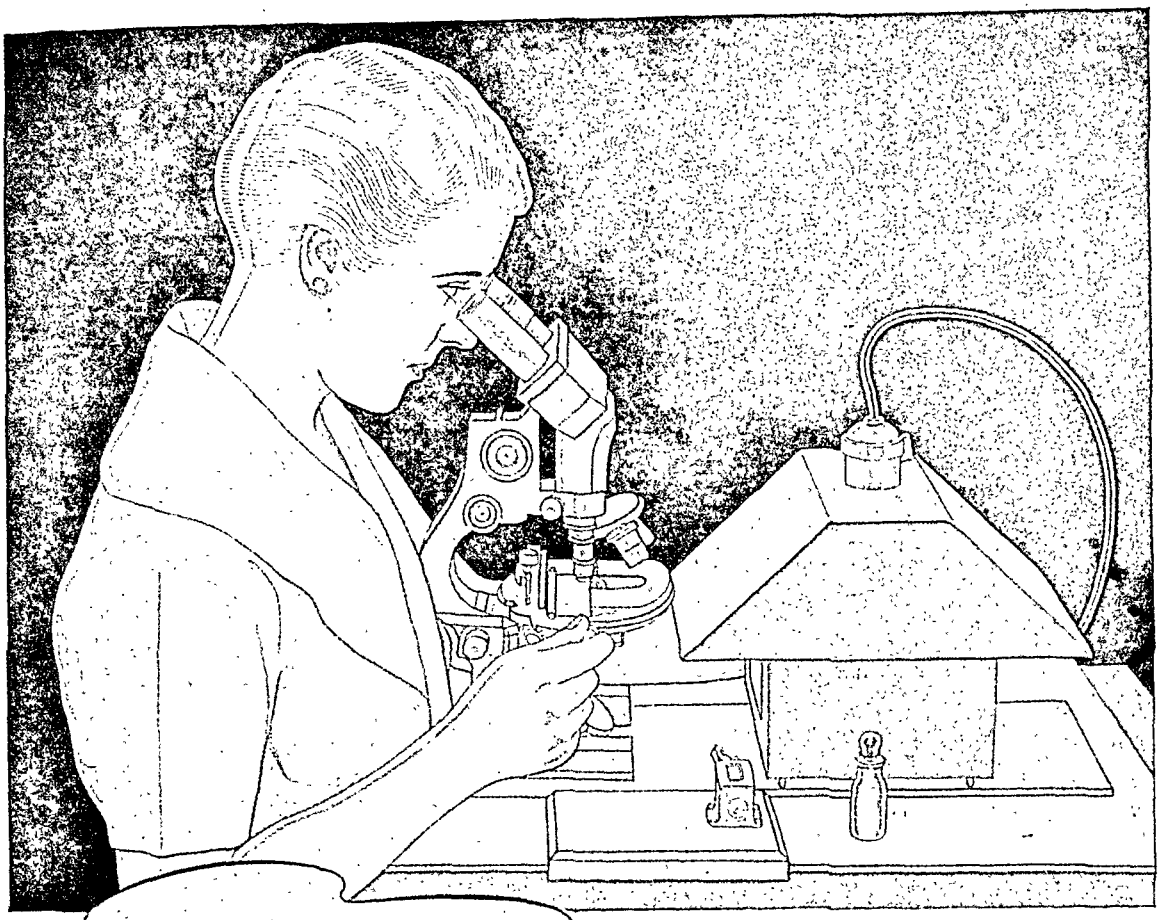
FELSEN, JOSEPH.

The Relationship of Bacillary Dysentery to Distal Ileitis, Chronic Ulcerative Colitis and Non-Specific Intestinal Granuloma. Ann. Int. Med., X, pp. 645-669, Nov., 1936.

Felsen contends that acute bacillary dysentery, acute and chronic distal ileitis, chronic ulcerative colitis and chronic non-specific intestinal granuloma have a common pathogenesis. The study includes 400 cases of acute bacillary dysentery, 29 cases of acute distal ileitis, 22 cases of chronic distal ileitis, 18 cases of combined chronic distal ileocolitis, and 84 cases of chronic ulcerative colitis.

The following data are presented in support of Felsen's contention.



Epidermiological Data.

In the United States the seaport cities are the chief endemic areas for bacillary dysentery. The general geographic distribution of acute distal ileitis, chronic distal ileitis, and chronic ulcerative colitis corresponds to that of bacillary dysentery. Outbreaks of dysentery in the New York area occur both in winter and summer, often in hospitals through improper isolation of unrecognized cases. Contact infection in chronic distal ileitis and chronic ulcerative colitis occurs chiefly during the stage of acute bacillary dysentery when the specific organisms are present in the feces, the incidence being 37.4 per cent in this series of cases. Conjugal infection is relatively common.

Clinical Data.

Acute inflammation of the distal ileum has been noted as an early manifestation of bacillary dysentery and clinically closely resembles acute suppurative appendicitis. A short prodromal period of nausea, headache and moderate pyrexia is followed by pain and tenderness in the right lower quadrant of the abdomen. Generally there is little or no rigidity, but the spastic ileum, or sigmoid may be felt. Felsen has seen acute distal ileitis with mesenteric lymphadenitis in no disease other than bacillary dysentery.

The transition stages from acute bacillary dysentery to chronic ileitis, or ulcerative colitis were noted by a study

The Antianemic Potency of 'Extralin' Is Assured by Careful Clinical Control

Pulvules 'Extralin'

(LIVER-STOMACH CONCENTRATE, LILLY)

For the Oral Treatment of Pernicious Anemia

● The advantages of 'Extralin' in the treatment of a disease where medication must be continued throughout the life of the patient are obvious. Its therapeutic efficiency as related to the size of the dose is greater than that of oral preparations of liver alone. Its administration in capsules is convenient and agreeable to the patient. Each lot of 'Extralin' is adequately standardized by use in actual cases of pernicious anemia before being released for sale.

'Extralin' (Liver-Stomach Concentrate, Lilly) is supplied in bottles of 84 pulvules and in bottles of 500 pulvules.

ELI LILLY AND COMPANY

INDIANAPOLIS, INDIANA, U. S. A.

of patients in the Jersey City epidemic, nine to twelve months later. These patients had persistent or recurring intestinal symptoms or signs, namely, diarrhea with blood, mucus and pus; watery diarrhea without gross blood; bloody evacuations without diarrhea, and miscellaneous intestinal disturbances such as recurring attacks of abdominal cramps. In some of the patients, visible evidence was also obtained roentgenographically, sigmoidiscopically, operatively, or at necropsy. In chronic ulcerative colitis, and ileitis "medicants' posture" has been frequently encountered.

The abortive, and atypical types of acute bacillary dysentery encountered recently fall into four groups; the asymptomatic, the meningitic, the appendicular, and the agranulecytoid.

Serological Data.

Diagnostic agglutination titers against B. dysenteriae were obtained in 22 cases of chronic, distal ileitis; 18 cases of combined ileocolitis; and 76 cases of chronic ulcerative colitis, or in 116 (93.5%) out of a total of 124 cases.

Bacteriological Data.

It is generally accepted that positive fecal cultures in acute bacillary dysentery are usually not obtained after the first or second week. In this series 10 out of 70 cases of chronic ulcerative colitis and ileitis were positive for B. dysenteriae. Bacteriophage was found in 20 out of 51 cases, while 100 normal controls showed bacteriophage in only one.

Aspirated fluid from inflamed joints in acute bacillary dysentery, chronic ulcerative colitis and ileitis has proved persistently negative upon culture.

Pathological Data.

In acute bacillary dysentery every case studied showed recto-sigmoid involvement. The earliest lesion is a hyperplasia of the solitary acuminate lymph nodules in a multiple and punctate fashion. There is an acute diffuse inflammation of the mucosa which is covered with a mucoid, blood tinged or purulent exudate. Bleeding occurs after the slightest trauma. Follicular necrosis quickly ensues and in severe cases the entire lymph nodule is eventually destroyed.

From the follow-up figures of the Jersey City epidemic 10 per cent of the cases had reached what Felsen calls the chronic phase of the disease. The ileum and colon show essentially the same pathologic process which is one of mural fibrosis and lymph nodule destruction. Here and there islands of mucosa remain intact and due to the blockage of ducts take on a polypoid appearance. A granulomatous lesion represents a productive type of inflammation. In general, the end-result is an ulcerated, narrowed, thickened, infected, vascularized tube of connective tissue.

Roentgenological Data.

Roentgenographic evidence of chronic ulcerative colitis or ileitis was obtained in 48 cases examined.

Felsen concludes his article with a discussion of the diagnosis and the therapy in acute and chronic bacillary dysentery. This is an unusually able study, well written, well illustrated and is worth reading in toto with care whether or not the reader agrees fully with the views of the author.

McGIBBON, J. E. G.

The Clinical Manifestations of the Spread of Carcinoma of the Esophagus Observed During Life. Brit. Jour. Surg., 24:86-104, July, 1936.

The author observed 100 cases of carcinoma of the esophagus over a period of seven years. The study included carcinoma located definitely in the esophagus and did not include growths in the postcricoid area or at the gastro-esophageal juncture.

DIET CONTROL

Where variables in diet must be reduced to a minimum, with maximum retention of nutritive elements, certain canned strained foods may be included to advantage. This is particularly true where seasoning must be omitted or controlled, fiber intake reduced and where ease of digestibility is a factor.

Scientific supervision of growing and preparation as employed by Gerber's Strained Foods, for example, provide a uniformity of product usually impossible under home methods. Seed selection and proper growing conditions provide vegetables of uniform as well as high quality. Elimination of delay in canning after picking affords protection often unobtainable in usual methods. The use of controlled processes of straining and cooking with air excluded, at specific temperatures, with only vacuum evaporation of moisture, retains minerals and vitamins in a high degree in addition to promoting a uniformity of product.

Gerber's exclusive shaker-cooking mechanically agitates each can to permit even cooking throughout, and reduces cooking time.

Obtainable, of course, without variation of quality at any season of the year.

CAL-BIS-MA - CAL-BIS-MA - CAL-BIS-MA - CAL-BIS-MA

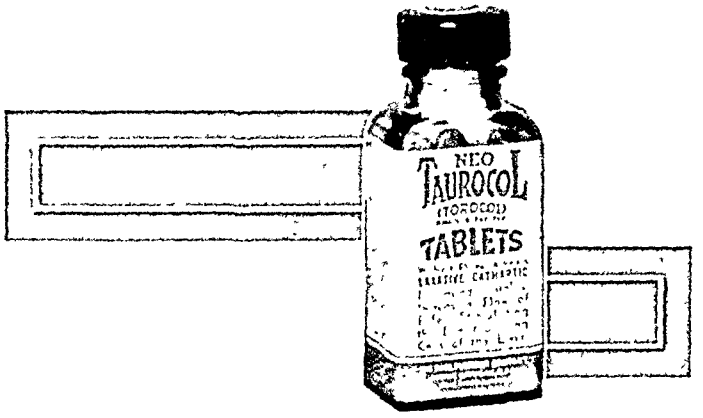
Gastric Hyperacidity

In the relief of gastric hyperacidity, *speed* is essential—Cal-Bis-Ma provides it. The neutralizing effect should be *prolonged* so as to prevent secondary acid rise—again Cal-Bis-Ma takes care of that. The irritated gastric mucosa should be soothed and protected from further irritation—that, too, is an important mission of Cal-Bis-Ma. Send for a trial supply and descriptive literature.

CAL-BIS-MA

WILLIAM R. WARNER & CO., INC.
113 WEST 18TH STREET · NEW YORK CITY

Cal-Bis-Ma (powder) is supplied in tins (with removable label) containing 1¾ and 4 ounces and one pound. *Tablets,* in bottles of 110.



In ninety-one of the patients dysphagia was the first and outstanding complaint; in four, the chief complaint was pain and in one, hoarseness. Two patients came for examination because of impaction of a foreign body in the stricture, and one patient sought medical advice because of enlargement of the cervical glands; in another, hiccough was the presenting complaint. The average duration of symptoms in the entire group was 3.4 months.

Twenty-nine patients showed clinical evidence of extension of the growth at the time of the first examination. Thirteen had paralysis of one of the recurrent laryngeal nerves; in eight, the left nerve was involved; in four, the right and in one case both nerves were paralyzed. The patient with hiccough was considered to have involvement of the phrenic nerve. Three patients showed involvement of the trachea without perforation, and in one a fistula was present. In four cases there were secondary implants in the esophagus. In other cases evidence of extension was present in the intercostal nerves and vertebrae, thyroid, pleura and pelvis. Thirteen of the series had postmortem examination and in ten of this group gross involvement of the lymphatic glands was demonstrated in the thorax or abdomen. Only one patient in the entire series was considered operable, but at the time of exploration the growth was found to be too extensive for removal.

The duration of esophageal carcinoma is divided into three periods: (1) the latent period, from the onset of the lesion until the beginning of symptoms, which is of unknown length; (2) the symptom period, from the onset of symptoms until the diagnosis is made, and in a group of cases selected from the literature this was found to be 5.7 months; (3) the manifest period, or that interval between the time that the diagnosis is made and the death of the patient, which was found to be 5.14 months.

A plea is made for early diagnosis in the hope that if the disease can be diagnosed at the beginning of the "symptom period," successful surgical removal of the growth may be accomplished.

Porter P. Vinson, Richmond, Va.

NEO-TAUROCOL

Bile Salts Without Phenolphthalein

Neo-Taurocol is a combination of bile salts, extract of cascara sagrada and aromatics. It increases peristalsis, and directly stimulates the liver cells, producing an abundant flow of bile.

OTHER PLESSNER PRODUCTS

TAUROCOL—stimulates the flow of bile without irritation to the liver or gastro-intestinal tract.

TAUROCOL COMPOUND—with digestive ferments. Especially indicated for intestinal indigestion and auto-intoxication.

VERA PERLES of Sandalwood Compound—indicated in certain subacute and chronic urinary diseases.

EXPERIMENTAL PHYSIOLOGY

DUFF, G. LYMAN.

The Nature of Experimental Cholesterol Arteriosclerosis in the Rabbit. Archives of Pathology, 22:2-161, Aug., 1936.

The author records the data from the study of a further series of experiments with cholesterol-fed rabbits which add much to the growing belief that the role of cholesterol in experimental cholesterol arteriosclerosis is a sequence of pre-existing primary lesions in the media and intima of the vessel wall. The presence of the primary lesion, as yet of unknown cause, permits a subsequent deposition of lipoids within and about it. The article should be read in conjunction with the former paper on "Experimental Cholesterol Arteriosclerosis and its Relationship to Human Arteriosclerosis," Archives of Pathology, 20:81 and 259, 1935 (reviewed in this Journal January, 1936).

Distinctly primary lesions in the ground substance of the intima are recognized in some instances before the deposition of any lipoid substance, and independent of similar lesions in the media. And of greater importance is the recognition of similar primary lesions in the media without corresponding change in the intima. In the media focal destruction of muscle fibres is observed prior to the accumulation of lipoids in the damaged areas. Arterial injury is looked upon as the initial event, and deposition of lipoids

NEEDS A BLAND, NON-IRRITATING NORMAL STIMULANT

The Problem—The objective of treatment in this prevalent condition should, of course, be the *restoration of normal peristalsis.*

Previous Failures—Clinical experience shows that normal bowel function cannot be obtained by the use of irritating cathartics, dehydrating salines, brans and other crude roughage demineralizing oily emulsions.

Corrective Therapy—By contrast the new development—Mucilose—a specially prepared hemicellulose obtained from the plantago leeflingii—does not irritate, does not stimulate gastric secretory function but acts correctively, naturally, to secure normal bowel rhythm

MUCILOSE
(STEARNS)

Supplies bland, non-irritating distention, lubricates without leakage, produces large, formed, soft stools is easy to take, economical

Mucilose is regulative to the spastic colon

as a subsequent one. Experimental injury of the walls of arteries by Scolowjew has demonstrated that this may be the case. By cauterization and by mechanical injury of segments of arteries in cholesterol-fed rabbits a more rapid deposition of lipoids takes place than in other parts of the vessels.

The importance of these observations in relation to the etiology and pathogenesis of human arteriosclerosis lies in the significance of focal injury to the wall of the artery by way of the vaso vasorum. The causes of such injuries may not be known now—but they may be assumed to be varied—mechanical, chemical, infection, etc. In the opinion of the reviewer this conception of the mechanism of arteriosclerosis meets the varied known factors of the disease much more logically than does the theory that it is the result of the primary effect of infiltrated lipoids from the blood stream through the intima.

BEAZELL, B. S., AND IVY, A. C.

Chronic Gastric Ulcer Following Bilateral Vagotomy in the Rabbit and in the Dog. Archives of Pathology, 22:2-213, Aug., 1936.

Bilateral subdiaphragmatic vagotomy was performed on thirty rabbits. Twenty-nine rabbits survived the operation and were fed a roughage diet. Twelve of the rabbits developed typical chronic gastric ulcer. Of the animals surviving fifty days, 50 per cent had ulcer. They occurred uniformly along the lesser curvature between the incisura and the pyloric sphincter.

Nineteen vagotomized rabbits living on a smooth diet presented ulcer in but three. That is, the soft diet decreased the incidence of ulcer by about one-half. As cutting the vagi produces gastric stasis, the additional factor of rough food with its attending mechanical trauma is another cause; though, the authors state, not the sole cause. The other factor is unknown.

Ulcer did not occur in sixty dogs which were subjected to bilateral vagotomy above the diaphragm and fed a soft diet. Meek reported the occurrence of two instances of gastric ulcer in thirteen vagotomized dogs fed on dry dog biscuit. Gastric stasis and trauma are therefore considered to be etiological factors in the development of ulcer in these animals.

N. W. Jones.

Lesions in the Pancreas and in the Anterior Hypophysis with Fatal Acidosis Following Prolonged Intravenous Administration of Glucose (In Dogs). Amer. Jour. Phys., 116, No. 1, 194-209, June, 1936.

Dogs were injected continuously with concentrations of approximately 50% glucose at the rates of .7-1.5 grams of glucose per kilogram per hour. Water was allowed ad libitum. Glucose utilization was estimated, and total urinary nitrogen, and carbon dioxide combining power of the blood. At death, which occurred in all cases, postmortem and histological changes were noted. They divide the course of the animal reactions into three phases: the first, without symptoms, of longest duration, in which animals appeared normal, associated with increased urinary nitrogen output, increasing glucose utilization, and slightly decreased carbon dioxide combining power; a second stage in which the animals showed weakness, restlessness, maximum glucose utilization, gradually diminishing carbon dioxide combining power, and nitrogen excretion; a third stage of stupor and coma followed by death, marked acidosis, and failure of glucose utilization. Pathological changes noted were chiefly hyperemic and congestive changes throughout the body tissues; the pancreas and hypophysis being markedly affected by this

PREVENT PUTREFACTION *and* PROLONG LIFE*

ZymenoL is a stable, palatable emulsion of the Enzymes and Vitamins B-G of Brewers Yeast in 60% pure Mineral Oil.

DOES NOT CONTAIN ANY IRRITANT DRUG

No Phenolphthalein
—No Cascara
—No Purgative

SAFE FOR INFANTS AND CHILDREN

Brings about daily bowel movement through the activity of the enzymes Invertase and Zymase of Brewers Yeast.

Evacuation results regularly from the natural impulse with a formed bulky stool without griping or irritation.

Doctors say:

"This therapy means putrefaction prevention and less putrefaction means a healthy bowel."

ZymenoL is rich in Vitamins B-G of Brewers Yeast known to aid in restoration of intestinal tonicity.

A Leader in Gastro-enterology Says . . .

"The recent advances in gastro-enterology have been of such magnitude and distinction that they engender in us a just pride and renew our determination to press forward toward our goal of perfection."

Dr. Ernest H. Gaither, Baltimore, Md., in his address at Kansas City before the section on gastro enterology and proctology of the A.M.A.

The American Journal of Digestive Diseases & Nutrition

- Now in its third year of publication—without alteration in its fixed principle of giving to the reading members of the medical profession the contributions of the best clinicians and investigators in the United States, Canada and Europe.
- So formulated, and edited by one of the most capable and select editorial groups in contemporary medical journalism, the Journal has made unusual progress during the comparatively short period of 30 months . . . today, the editorial office is constantly in receipt of very valuable manuscripts which collectively form a cross section of new gastro-enterological thought.
- The absence of "politics" from this set-up ensures to the reader an unbiased preliminary evaluation of submitted material by men pre-eminently qualified to judge the worth of MSS in the various sub-fields of this broad specialty.
- Meeting the growing difficulty of prompt publication, the Journal is constantly diminishing its back log of material by insistence more and more, as time goes on, upon the idea of BREVITY in writing.
- The American Journal of DIGESTIVE DISEASES and NUTRITION is not only making friends but it is KEEPING friends. The renewal percentage each year and each month is a positive proof of the sound, month-by-month value of the publication, and it is recognized that this Journal provides today, as no other publication ever provided, a trustworthy postgraduate education in a field much more intricate and fascinating that has been generally supposed.
- Once upon a time gastro-enterology was generally regarded as a specialty contaminated by faddism and quackery, but the pioneers, many of whom are still living and active on this editorial board, have lifted it to the level of a strictly ethical study—and the Journal is playing an important role in facilitating this important branch of medical practice.

An Open Letter to the Physicians of North America

Do you realize that 60 per cent of all symptoms in general practice arise from the digestive tract?

Many diseases are intrinsic, and many at a distance reflect their symptomatology with great facility in the alimentary canal . . .

Is diagnosis of digestive diseases easy?

Apparently not. The old rule of thumb,—"appendix, ulcer, or gall bladder" is no longer useful. We are becoming gradually acquainted with the disorders and diseases of the colon and reducing this information to some semblance of order. Physiology, bacteriology, chemistry, parasitology, clinical observation, animal experimentation, roentgenology, nutrition, allergy and psychology are the organized methods of approach to a fuller knowledge of digestive diseases. And there still lies beyond, the *dark continent* of the small intestine, concerning which so little is positively known.

To the scholar, what is offered by this Journal is indispensable.

To the man too busy to indulge his yen for applied research, may we say this,—an hour a month with the American Journal of DIGESTIVE DISEASES AND NUTRITION will provide the key to *practical success* in this most important, difficult, but "treatable" field.

Spend $6.00 for a year or $10.00 for 2 years NOW. Join the increasing group of doctors who enjoy this periodical. The card below is attached for your use, and is postage free.

change, hyperemia of the pituitary was chiefly limited to the anterior lobe. The pancreas in most cases showed engorgement, and gross hemorrhages. The liver showed enlargement, hemorrhages in the parenkyma and marked glycogen storage. Glucose administration caused death in all cases, even those receiving the minimum dosage. The pathological changes were roughly proportional to the quantity and rate of glucose administration.

The Vasomotor Effect of Acetylcholine on the Stomach of the Dog. Amer. Jour. Phys., 116, No. 2, 330-336, July, 1936.

Experimental studies were made on the rate of blood flow in the stomach of the dog when perfused with acetylcholine. Three types of preparation were used: isolated stomachs supplied by a perfuser dog; stomachs in situ with innervation intact; and isolated stomachs with metal oncometer. Measurements of blood flow, and motility were made in the same preparations, volume changes were measured separately; acetylcholine was administered by single injection or by continuous injection with the Woodyatt pump. The authors observed diminished blood flow in 63% of the preparations with small doses of acetylcholine, but increased flow with larger doses. This biphasic effect was not due to physiologic rebound as it was constant with continuous injection of acetylcholine. The biphasic effect was not noted in the oncometer preparations, a constant volume increase being noted even with small doses. They conclude that the physiologic amount of acetylcholine is probably approximate in concentration to their "small dosages" of acetylcholine, and may therefore restrict blood flow, thereby being an etiologic factor in peptic ulcer.

APPELY, F. L., AND CARY, M. K.

The Chloride and Alkali Content of the Duodenal Secretions and Their Relation to Gastric Acidity and Emptying Time. Amer. Jour. Phys., 116, No. 2, 337-342, July, 1936.

Experiments were undertaken to shed some light on the factors involved in the regulation of hydrochloric acid in gastric secretion as related to neutralization and dilution by diluting fluid secreted or regurgitated from the duodenum; and the relation of these factors to gastric emptying time. Hydrochloric acid test meals were given containing definite concentrations of determinable substance (glucose, iron, dye or urea) at 15 minute intervals samples were withdrawn and determinations made for total chloride, acid, and the substance indicating dilution, neutral chloride was determined by subtracting total from free, and the alkali and chloride in the diluting fluid calculated by formula. They find that acidity is reduced chiefly by dilution and to small extent by neutralization; rate of reduction of acidity varies directly with emptying rate. The rate of reduction of acidity varies inversely as the concentration of neutral chloride and alkali in the diluting fluid. They conclude that acidity depends on the character of the diluting fluid, and that necessarily fluid regurgitating from low in the duodenum and jejunum leads to low acidity, the process being reversed in high acidity.

THIESSEN, N. W.

The Vascularity of Benign and Malignant Lesions of the Stomach. A comparative study with clinical correlations. S. G. O., Vol. 63, No. 2, pp. 149-156, Aug., 1936.

The author, wishing to throw some light on the so-called vascular theory of the causation of ulcer and carcinoma of the stomach, studied 57 resection lesions using histologic methods and methods of injection.

All blocks taken for study were cut in the same manner and compared with sections taken from normal areas of the same specimen. A number of specimens were injected with mercury and roentgenograms made of their vascular patterns. Indices of the vascular density of the specimens were determined and studied in relation to each other and in relation to mortality. In the benign ulcers it was found that the vascularity of the tissue near the lesion was half again as great as in the rest of the stomach. In the case of the carcinomatous lesions the data is suggestive that the patients who lived longest had the more highly vascular lesions.

The author comments that the gradation of vascularity from normal tissue up through benign lesions to fully developed carcinomata does mean something. He suggests that the increased cellular activity in such lesions, and the increased metabolic rate as Warburg contended, requires a greater blood supply.

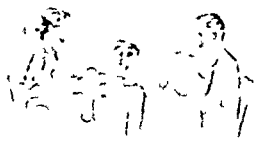
An appendix, a bibliography, two tables, and five figures accompany the article.

Nelson M. Percy, Chicago.

An Aseptic Method of Temporary Valvular Enterotomy. S. G. O., Vol. 62, No. 6, pp. 1006-1009, June, 1936.

The author describes an aseptic method of temporary valvular enterotomy using a metal tipped rubber tube. The metal tipped rubber tube is fitted with an obturator with a cutting point.

THOROUGHLY BLAND....



CREAM of WHEAT

Mechanically as well as Chemically . . .

Yet Tasty and Appetizing

For the Infant's First Cereal Food Cream of Wheat may be safely prescribed without a thought of intestinal upset. It is readily digested and assimilated

For the Breakfast Energy Needs of the Entire Family Cream of Wheat helps supply the calories needed during the morning working hours because it leaves the stomach rapidly and is promptly assimilated

When a bland highly nutrient food is indicated

●

An Economical Food Value because the large package makes six and one half quarts of cooked cereal fifty two generous servings at less than a half cent per serving.

When a bland diet is required, Doctor, one that is not only mechanically non-irritant but also does not evoke too much of acid gastric juice, Cream of Wheat deserves your consideration.

Needless to say, Cream of Wheat is not a medicamentum. It is a cereal food of uniform granular consistency and appealing taste which has earned for it an established position in the dietaries of millions. In untold American households, it is the preferred cereal for infants, children, and grownups.

Because of its physical and chemical nature, Cream of Wheat possesses distinct advantages which may be termed therapeutic due to their value in many specialized diets. When cooked, it consists of soft, macerated wheat particles, entirely devoid of irritating bran. Hence it may safely be given to patients afflicted with peptic ulcer, the various dysenteries, colitis, and those recovering from medical and surgical affections of the gastro-intestinal tract. Since it is rich in carbohydrate, it evokes a minimum flow of acid gastric juice, an important point in ulcer therapy. Because of these advantages, and because of its excellent caloric content (115 cal. to the ounce) Cream of Wheat is a welcome addition to the at times too bland "bland diet."

ACCEPTED AMERICAN MEDICAL ASSN.

THE CREAM OF WHEAT CORPORATION

MINNEAPOLIS, MINN., U. S. A.

Hematemesis and Melena

Creamalin

The Specially Prepared
Colloidal Cream of
Aluminum Hydroxide
for

PEPTIC ULCER

According to Rivers, 75% of the cases of hematemesis and melena are due to peptic ulcer. Bleeding ulcers have proven to be especially amenable to Creamalin therapy. Creamalin produced an immediate reduction of the hyperchlorhydria usually associated with bleeding ulcer, thus attaining the first important therapeutic objective. Combatting the hyperchlorhydria is important because the excess acid not only has its usual irritant effect on the ulcerated mucosa, but also, as pointed out by Alvarez, acts to digest the blood clot, thereby causing a recurrence of hemorrhage. The unique astringent properties of Creamalin may also be a contributing factor in obtaining rapid control of hemorrhage.

Because of its unusual antacid, astringent, and healing properties, Creamalin should be given first consideration in all cases of bleeding ulcers since it permits fulfillment of a desirable therapeutic stratagem, namely, to treat the ulcer while attempting to control the hemorrhage.

Creamalin can be administered orally or by continuous drip using the new Creamalin Automatic Drip Control. Material for clinical trial and reprints of published studies on request.

CLEVELAND CHEMICAL ASSOCIATES
3616 Euclid Avenue
Cleveland, Ohio

The obturator may be projected through the metal tip of the rubber tube and withdrawn again by digital pressure.

The author advises a technic in which the tip of the tube is buried against the bowel wall and fastened in place by means of two concentric sutures around the site chosen for the enterostomy. The cutting point of the obturator is then forced through the bowel wall and retracted again into the rubber tube. The tube is now pushed through the opening by a rotary motion and covered over by folds of bowel wall following the method of Witzel over a distance of from 3 to 5 cms. This position of the bowel is now secured to the parietal peritoneum with a layer of omentum intervening, and the tube is placed in the lower angle of the wound. The wound is closed with interrupted sutures and the tube fastened in place by means of a snubbing stitch.

Seven figures and a bibliography accompany the article.

NUTRITION

SHAPIRO, A., AND KOSTER, H.

The Influence of Bile on the Excretion of Sterol in the Feces. Amer. Jour. Phys., 116, No. 2, July, 1936.

These authors studied the excretion of ether soluble material and determined sterols in the unsaponifiable fraction by digitonin precipitation, in the stools of two patients having "T" tubes in the common bile duct such that the bile could be admitted to the intestine, or excluded at will. They found that total ether soluble substance was increased to 3-4 times the normal when bile was excluded from the intestine. These findings are consistent with those of other investigators. Sterols were increased over the intake value in all cases, whether bile was present or absent in the intestine, but was diminished in the absence of bile as compared to control periods when it was admitted to the intestine; this is in contrast to the findings of Sperry in dogs. The authors conclude that sterol excreted in the feces is greater in human subjects when bile is present in the intestine than when it is excluded, and that this finding may vary from those observed in dogs due to a greater cholesterol content in human, than in dog bile.

SVIRBELY, J. L., AND KENDALL, E. C.

Vitamine C and the Adrenal Cortical Hormone. Amer. Jour. Phys., 116, No. 1, 187-193, June, 1936.

An attempt was made to show the relation between vitamine C and adrenal cortical hormone, in the prevention of scurvy in two adrenalectomized dogs, and in guinea pigs. Nitrogen balance studies were made on two adrenalectomized dogs on a vitamin C free diet and maintainance dosage of cortin. These animals failed to develop scurvy in 106 and 230 days respectively. Variations in nitrogen balance appeared due to inadequate cortin dosage. In guinea pigs on vitamin C free diet, adrenal cortical hormone failed to prevent or cure scurvy.

I. S. Cherry, Chicago.

GRAY, J., KIM, M. S., AND IVY, A. C.

Is a Portion of the Pancreatic Secretory Response to a Meal Due to the Absorption of Digested Food Products. Amer. Jour. Phys., 116, No. 1, 210-213, June, 1936.

In an experimental study to determine the effects of split-protein products; dextrose, and emulsified fats, on pancreatic secretion in acute and chronic pancreatic fistula dogs; these substances were injected intravenously after adequate control periods, and the secretory response checked by threshold doses of secretin. As protein split-products, liver extract (fraction active in pernicious anemia) and Witte's peptone were used. The liver extract, with vasodepressin substance removed, produced no secretory response. Witte's peptone intravenously caused slight temporary increase in secretion, but after 20-30 minutes the pancreas became refractory to further large doses, though the response to secretin was augmented. No response was observed on introduction of these substances into the intestine. Dextrose and emulsified fats produced no secretory response. It was concluded that secretin appears to be the sole humoral excitant of pancreatic secretion following a meal.

I. S. Cherry, Chicago.

ROENTGENOLOGY

YATER, WALLACE M., OTELL, LAURENCE S., AND HUSSEY, HUGH H.

Hepatosplenography with Stabilized Thorium Dioxide Sol: A follow-up study of 200 patients examined over a period of five years. Radiology, 27:4-391, Oct., 1936.

This valuable article deals with 200 patients examined over a period of five years. The amount of solution administered in the average case contained a quantity of thorium dioxide equivalent in alpha-ray activity to from 1.5 to 3.0 micrograms of radium. The beta-ray and gamma-ray activity is probably insignificant. After a period of five years it is evident that a large amount of the metal remains present in the body, but some of it is mobilized from the original reticulo-endothelial cells in which it was deposited. The dose for each pound of body weight at present used by the authors is 0.5 c.c. of the stabilized colloidal solution of thorium dioxide containing approximately 22% of metal by

F. H. PAXTON & SONS, INC.
469 E. Ohio St. Chicago, Ill.

volume. One-third of the total dosage is usually injected intravenously on each of three successive days, and films made thereafter on the fourth or any successive day.

The useful objects of the test are as follows: (1) In determining the nature of a mass in the upper part of the abdomen. (2) To determine the presence and kind of hepatic disease (atrophic cirrhosis, hypertrophic cirrhosis, syphilis of the liver, metastatic malignant lesions, primary tumor, abscess, cyst, and amyloidosis). (3) To ascertain whether metastatic lesions are present in the liver if operation is contemplated for carcinoma. (4) To demonstrate rupture of the liver or spleen. (5) To determine the cause of jaundice (whether intrahepatic or due to obstruction of the common duct). (6) To follow the progress of hepatic or splenic disease. (7) To demonstrate whether a lesion is above or below the diaphragm. (8) To diagnose ascites.

There are no contraindications established as yet for the procedure. No reactions have occurred. No harm has been observed in the liver even in cases of acute hepatitis. Of the 200 cases, the diagnosis was proved in 73 cases. The diagnosis by hepatosplenography was correct in 67 cases; incorrect in 6. Of the 6 incorrect diagnoses, 4 had metastatic lesions in the liver which were unsuspected in spite of the procedure, in another case primary carcinoma was diagnosed as metastatic carcinoma, and in one case cirrhosis of the liver was not diagnosed.

Stated in other words, out of the 200 cases the clinical diagnosis was confirmed in 61; the diagnosis was made from the hepatosplenograms in 49 cases; the procedure was used to eliminate or to establish the presence of metastases in 46 cases; and it was of negative value in 35 cases; wrong in 6 cases. The majority of the 200 patients were suffering from some fatal malady. Of 47 who are still living, 11 have had the thorium between three and four years, and 14 between four and five years. The first patient injected is still living and well, in spite of a chronic leukemia. Of the 47 patients known to be living, 36 have been reexamined either at intervals or within very recent date. A number of them were cases of cirrhosis of the liver, but clinical studies, including the bromsulphthalein test, have showed markedly *little progression in the severity of the* disease in most cases. There has been no increase in susceptibility to infection. A preliminary histopathologic study in 71 cases indicate that the presence of thorium dioxide has not caused appreciable organic changes. The authors predict that hepatosplenography with stabilized thorium dioxide sol will come to be recognized as an essentially harmless diagnostic procedure.

James T. Case, Chicago.

MERRITT, E. A.

Radiation Therapy of Inoperable Intra-abdominal Malignancy. With special reference to the stomach. Amer. Jour. Roent., 36:3-324, Sept., 1936.

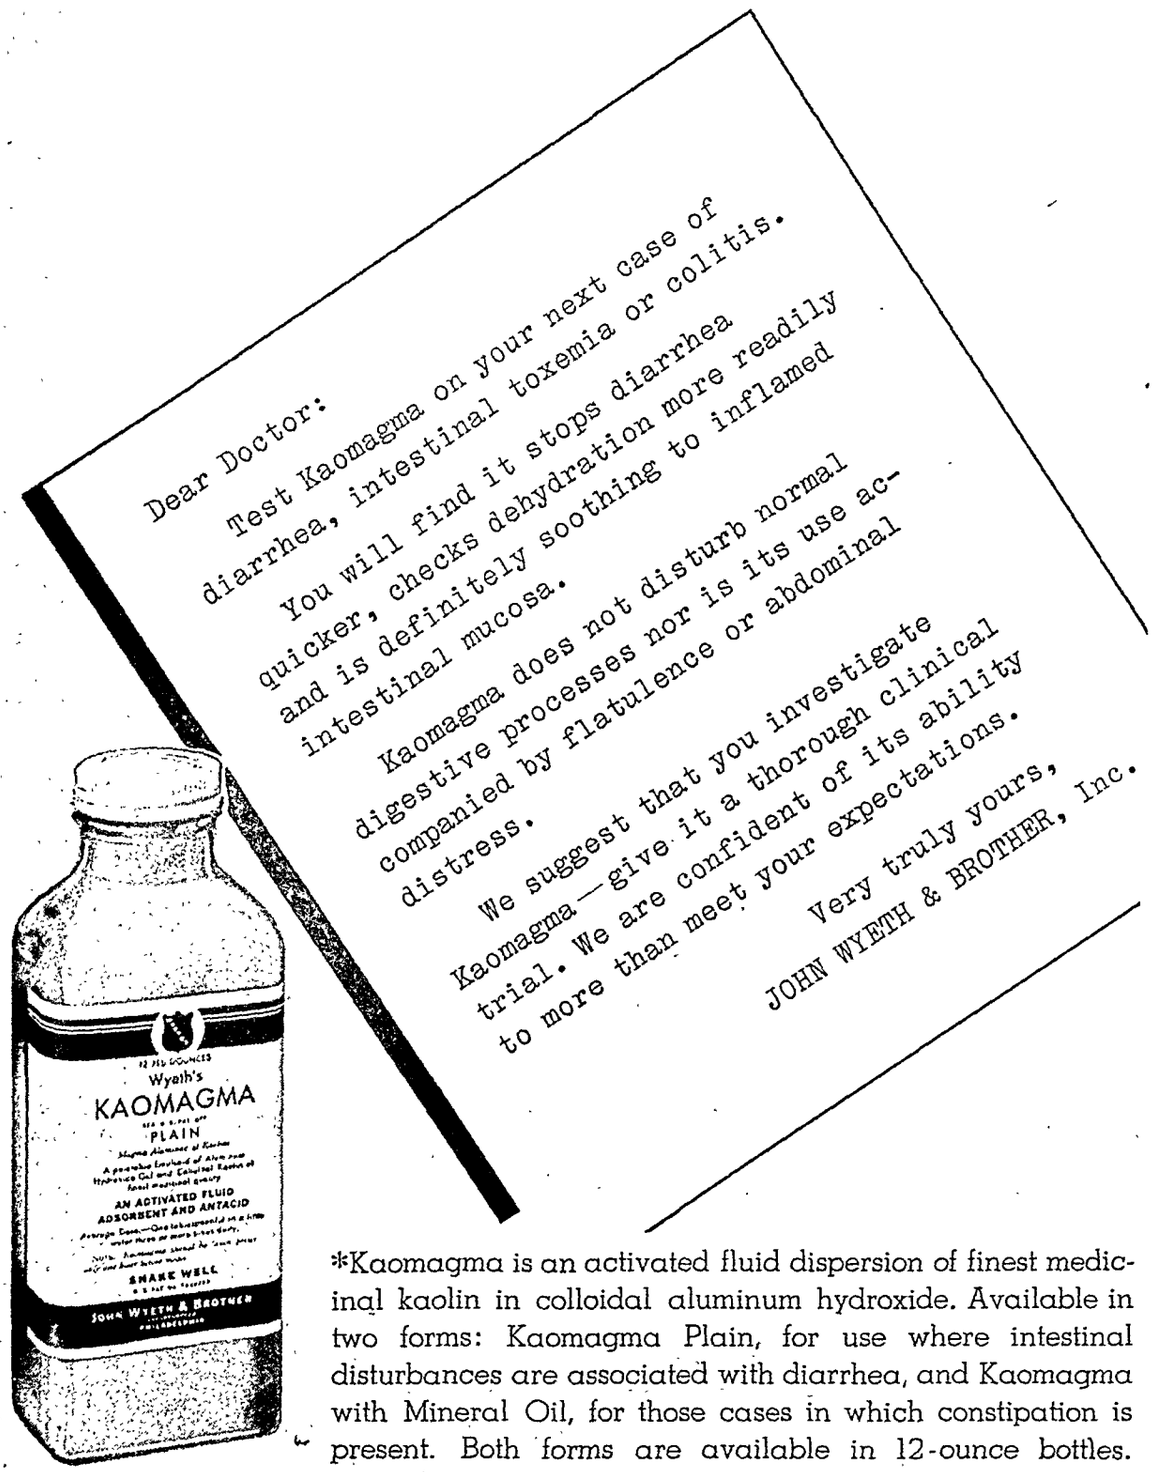
Sporadic attempts at roentgen treatment of inoperable gastric cancer have been reported since 1903. The author has advocated pre-operative irradiation of obscure abdominal tumors for some years and has never observed that it delayed or prevented recovery. On the other hand, he states that he has proof of its very great value as a life giving measure. Now that the fractional method of Coutard or its modification is coming into general use, malignant newgrowths of the stomach as well as other suspected intra-abdominal tumors should be treated with roentgen irradiation when operation is not available. If the lesion is resectable, Merritt does not advocate irradiation. Case reports are published concerning four patients.

James T. Case, Chicago.

JORDAN, S. M.

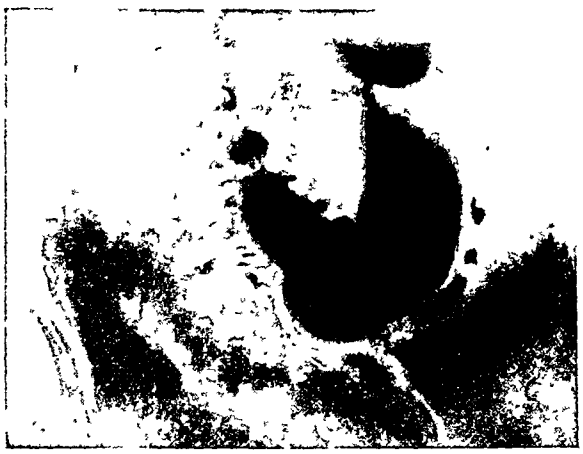
A Review of the Gastric Ulcer Problem. J. A. M. A., 107:1451, Oct. 31, 1936.

In this study 119 cases have been used in which the diagnosis of gastric ulcer had been made and checked either by surgical exploration or by follow-up studies varying from a few months to eleven and one-half years after medical treatment. Sixty-two of the cases were men and fifty-seven were women.



The first question which arises upon X-ray examination is, is the lesion organic? Spasm, adhesions, cicatrization of an old lesion, and a loop of small intestine distorting the stomach may cause confusion. A prepyloric constriction is the most likely to cause trouble, simulating an annular carcinoma. It may occur independently or with cholecystitis, appendicitis, duodenal ulcer, or an ulcer of the middle of the stomach. It can be relieved by ulcer therapy or treatment of the underlying cause. Sometimes after its relief the real lesion is found in the duodenal cap, while other times the true cause is not known.

Adhesions may so deform the stomach that it may be difficult to determine whether the lesion is a malignancy, an old lesion, or a new one. In some cases of this series an hour glass deformity was found, which at operation turned out to be adhesive bands around the middle of the stomach, or the cicatrix of a posterior wall ulcer.



The silhouette of a loop of jejunum or the third part of the duodenum against the lesser curvature may give the appearance of an irregular area which resembles a carcinoma or an ulcer with a smooth crater.

To those who have never used

KAOMAGMA*

*Kaomagma is an activated fluid dispersion of finest medicinal kaolin in colloidal aluminum hydroxide. Available in two forms: Kaomagma Plain, for use where intestinal disturbances are associated with diarrhea, and Kaomagma with Mineral Oil, for those cases in which constipation is present. Both forms are available in 12-ounce bottles.

Treatment of Ulcers

and gastro-intestinal diseases

Horlick's Malted Milk provides a well-balanced bland food and adds variety to the prescribed diet

PATIENTS suffering from ulcer or gastro-intestinal diseases can be relieved from a monotonous diet program by the use of Horlick's Malted Milk. This bland food, so easily digested, is extremely useful as a variant when brought into the dietary two or three times a day. Many persons dislike plain milk and thus by giving them Horlick's they are more apt to respond to the necessary diet.

Horlick's is a partially predigested milk and grains food, is nourishing and practically free from insoluble residue In ulcer cases it can readily be used as a carrier for mucin.

Horlick's can be mixed with water or milk and caloric intake can be increased or decreased as required.

In ulcer cases, the Tablets are a special convenience, since a flask may be carried in the pocket, offering suitable nourishment at the required intervals.

HORLICK'S
THE ORIGINAL
MALTED MILK IS
WITHOUT AN EQUAL

There is no satisfactory substitute for Horlick's to get results Many imitations are merely mechanical mixtures of raw cocoa, skim milk, inferior malt powder and ordinary sugar. Patients do not tire of the Horlick flavor, as they do of sugar-loaded products. Give your patients the benefits of Horlick's the Original.

The next question which arises is, is the lesion benign or malignant? This can be answered by the history, by gastric analysis and by X-ray examination. The history must consider the duration of symptoms and any recent changes of symptoms, the absence of food relief and the frequency of vomiting, loss of appetite and weight. Gastric analysis usually shows no acid in malignancy while in ulcer there is acid present.

In the X-ray study of the lesion the original appearance of the lesion must be studied and the changes it undergoes under trial treatment. The ulcer is considered healed only when the crater completely disappears. The ulcer of the pars media, lesser curvature, is usually benign, while the less common prepyloric lesion and lesion of the posterior wall are more likely to be malignant.

In order to safeguard against a present malignant condition or future malignant condition the management must be limited in time and careful follow-up studies must be made. The complete disappearance of the ulcer requires three to eight weeks and sometimes in lesions of the posterior wall even longer.

The question of surgical intervention can be answered by saying that where malignancy is suspected, or where it is thought recurrence may take place with possible malignant degeneration, surgery should be done.

After healing of the ulcer it has also been observed that those patients who live carefully are not as prone to recurrences as those who do as they please.

BEST, R. R., AND HICKEN, N. F.

Cholangiographic Demonstration of Biliary Dyssynergia. J. A. M. A., 107:1615, Nov. 14, 1936.

In this paper the authors present clinical and X-ray evidence of spasm in the lower end of the common duct They also discuss their work in injecting radiopaque substances into the common bile duct during operation. The solutions they have used for this are lipoiodine, tharium dioxide solution and hippuran in 48 per cent aqueous solution. Immediately after the injection of the fluid roentgenograms are taken. If it is believed necessary they are repeated later and have been found valuable in ascertaining why biliary fistulae fail to close, or spasm of the common duct.

The authors believe immediate cholangiography at operation to be of value in demonstrating common duct stones which may not be palpable, in diagnosing pancreatitis or tumors of the head of the pancreas, and to determine the patency of the cystic duct.

In addition the authors attempted to verify the idea that some cases of gall bladder colic were due to spasm of the sphincter of Oddi. They did this by injecting, postoperatively radiopaque substances into the bile ducts either through a catheter left in the cystic duct, in the common duct, or a T tube. They found this spastic biliary dyssynergia to exist in 15 per cent of 75 cases.

The spasm of the sphincter was sometimes relieved by the injection of the warm opaque substances. They also found that glyceryl trinitrate tablets, magnesium sulfate, atrophine, belladonna, cream, and olive oil relieved the spasm.

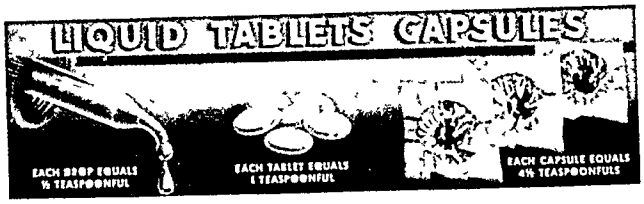
YOU WOULDN'T PRESCRIBE MA HUANG FOR THE PATIENT NEEDING EPHEDRINE

ACCEPTED AMERICAN MEDICAL ASSN Council on Pharmacy and Chemistry

The trend of modern medicine is to prescribe active principles in concentrated and agreeable forms.

In line with this trend, White's Cod Liver Oil Concentrate affords you the active principles of cod liver oil—the natural vitamin "A" and "D" potency fractioned from the natural oil of gadus liver; not a synthetic, not a substitute, but the therapeutic potency of cod liver oil minus the inert and objectionable fatty bulk.

This natural, concentrated product, 100 times the potency of cod liver oil* is available for clinical use in three convenient, economical dosage forms to suit every type of patient.



For Infants—Liquid Concentrate—two drops of this concentrate equal one teaspoonful of cod liver oil.*

For Youngsters and Adults—Tablets—each candy-like tablet equals one teaspoonful of cod liver oil.*

For Reinforced Dosage—Capsules—each clear, soluble capsule equals four and one-half teaspoonfuls of cod liver oil.*

Recognition of the marked advantages of this concentrate form of medication is attested by the rapidly increasing demand for the three dosage forms of White's Cod Liver Oil Concentrate. It is promoted ethically, and is not advertised to the public.

after careful preparation of the bowel. Hemorrhoids are treated mainly by injection.

A lesion diagnosed non-malignant by a single biopsy examination may prove to be malignant if biopsy is repeated from a different part of the tumor. Schmieden and Westhues believing that all carcinomas of the rectum develop from a polyp regard radical operation absolutely necessary when a polyp is found, whereas the author agrees with Maresch that only seven per cent of polypi degenerate into carcinoma and suggests a proctoscopic examination every three or four months would preclude overlooking a malignant degeneration. Results comparable with the abdominoperineal operation are reported by the sacral method of operation with retention of the anal sphincter. Surgical intervention in the presence of colloid carcinoma is futile. No benefit has been observed from X-ray or radium therapy except in anal carcinoma in which case radium supersedes surgery.

Chronic proctitis is considered one of the most frequent rectal diseases. Four stages are described. They are designated proctitis mucosa, ulcerosa, granulosa, and atrophicans. The granulosa stage represents the healing of the ulcerosa form and proctitis atrophicans is the end stage. *The method of treatment is omitted.*

In anal eczema and pruritus not due to such general diseases as uremia, diabetes, et al, the main etiologic factor is proctitis. The secretion from the diseased mucous membrane is responsible for the skin changes and symptoms. Treatment consists of shaving and cleansing the perianal skin, removing condylomata, applications of silver nitrate or tannic acid solutions to the skin, local treatment of the proctitis, subcutaneous injections of plenocain at the edge of the eczematous area, and oral sedation (translated by Julius Gerendasy, M.D.).

Reviewer's Note:

Whether the opinions expressed in this article are those of an individual or are representative of Europe they are different from those of leading proctologists in this country. As evidence of this divergence of opinion mention may be made of the percentage of malignant degeneration in polypi, the choice and types of operation for carcinoma, the beneficial effects of radiation therapy, views on the subject of proctitis, and results in the treatment of pruritus.

ROBERTSON, JARRETT P., AND SHARP, LEE.
Granuloma Venereum and Lymphopathia Venereum. Amer. Jour. Surg., 34:2, 322-3, Nov., 1936.

Considerable confusion exists regarding two diseases, granuloma inguinale and lymphogranuloma inguinale, probably largely as a result of the similarity of names and their venereal nature. Granuloma venereum and lymphopathia venereum have been suggested for general use as being more descriptive of the conditions.

"Granuloma venereum is a chronic disease which destroys the skin and subcutaneous tissue, spreads slowly by continuity and contact but does not involve the lymph nodes and deeper structures." The laboratory diagnosis is made by finding Donovan bodies (Gram negative encapsulated bacilli) in epithelial cells removed from the lesion. The clinical diagnosis depends on the history, local examination, and response to specific therapy. It must be differentiated particularly from chancroid, chancre, and sometimes the primary lesion of lymphopathia venereum. The Ito-Reenstierna skin reaction and search for Ducrey's bacillus are commonly used as is the dark field examination. Fuadin gives 40 per cent quicker healing, is less toxic, and allows fewer recurrences than does tartar emetic.

"Lymphopathia venereum is an acute, subacute, or chronic adenitis of venereal origin." It is a disease of the lymph channels and nodes. The microscopic picture of tissue resembles closely that of tuberculosis. The intradermal test made with Frei antigen is of the greatest aid

A STRIKING ACHIEVEMENT

WINTHROP

BETAXIN

TRADEMARK

The synthetic production of vitamin B_1 in pure form represents a distinctive chemical achievement. Vitamin B_1 is recognized as a dietary essential for infants, children and adults.

The first synthetic vitamin B_1—Betaxin—makes available to physicians an adequate and economical supply of this dietary essential and antineuritic factor. According to clinical reports vitamin B_1 is indicated not only in *beriberi*, but also in less severe B_1 avitaminosis characterized by *anorexia, gastric and intestinal atony*. Its use is also suggested in pregnancy and lactation, when metabolism is increased, as in hyperthyroidism and infections, and in various nervous disorders of nutritional origin.

•

How Supplied: For oral administration tablets of 0.1 mg. and 1 mg., bottles of 50; for intramuscular injection, ampules of 1 cc. (= 1 mg.), boxes of 10. For research laboratories, crystals in vials of 15 mg. and 50 mg.

Each milligram is equivalent to 500 international units.

RIDDOCH, J. W.

Anal Fissure. The Lancet, 2:20, 1150-1152, Nov. 14, 1936.

In spite of the fact that fissure is one of the commonest of anal conditions there is a lack of unanimity of opinion regarding its cause, chronicity, and rationale of cure.

According to Ball, fissure resulted from a tearing down of a rectal valve by a scybalum, the valve forming the sentinel pile. As a modification of this theory it was suggested that a small subcutaneous sinus develops following rupture of an anal valve, the fissure resulting from the giving way of the roof of the sinus. The most recent view is that most fissures result from the tearing of a "pecten band" by a hard fecal mass.

Chronicity has been ascribed to spasm, scar tissue formation during attempts to heal recurring tears, and infection.

The upper two-thirds of the anal canal which is lined by mucous membrane is separated from the lower one-third which is lined by skin, by the pectinate line (the level of the anal papillae). The band of skin extending from 3 to 9 mm. below this line has been called "pecten," the "anal intermuscular septum" being firmly attached immediately under the pecten. This septum separates the *internal sphincter muscle from the subcutaneous portion* of the external sphincter and into it is inserted the fibrous prolongation of the longitudinal muscle of the anal canal. The key to this discussion is this septal region. The superficial external sphincter lies outside this ring and is arranged in an elliptical manner, the fibres from each side attaching to the central point of the perineum forming a wide angle and the fibres attaching to the anococcygeal raphe and coccyx forming a sharp angle. The support from this muscle to the septal ring is especially weak posteriorly and less so anteriorly.

The author suggests that trauma such as the passage of large hard scybalae causes rupture of the most rigid part of the canal, the septal region, at the points posteriorly and anteriorly where the support is deficient. The damage may be in the nature of small extravasations of blood followed by fibrous tissue formation and contraction with formation of a ridge of fibrous tissue which ruptures with passage of a hard fecal mass.

Chronicity is due to narrowing of the anal canal at the septal ring produced by contraction of scar tissue and deficient blood supply. Spasm may be of some importance but it is not a decisive factor.

The avoidance of overstretching of the anal canal and increasing the blood supply by stimulating applications or injections are the principles of treatment. The injection treatment may be useful in selected cases but it is not ideal because of increased scar tissue formation, lack of healing even after repeated injections in some cases, and in others persistence of pain with defecation even when healed.

The author's surgical method is commonly used in the office or clinics. The region to be incised is infiltrated with an anesthetic solution. A slotted anoscope is inserted with the slot and fissure corresponding. The anal intermuscular septum is incised while under tension until the

NEW
REDUCED PRICES
on
Decholin
REG. U.S. PAT. OFF.

Effective January 11, 1937, the price of Decholin tablets will be substantially reduced.

This drastic reduction is made possible by savings in quantity manufacture brought about by the constantly widening use of Decholin, the medication of choice in the medical management of gallbladder and biliary tract disturbances. Through its choleretic and cholagogue influence Decholin is of proved value in chronic cholecystitis, hepatitis of toxic origin, non-calculous cholangitis, biliary engorgement, functional hepatic insufficiency.

The savings which quantity production has made possible, we desire to pass on to your patient. Doctor. These are the new low prices, showing a reduction of from 20% to 28%.

Price to patient	Old	New
Decholin, package of 100 tablets	$4.50	$3.60
Decholin, package of 25 tablets		$1.00

(At former price of 1¢'s)

Because of these new prices, Doctor, we sincerely hope that Decholin will find still wider use in your practice.

Riedel-de Haen, Inc.
105 Hudson Street, NEW YORK, N. Y.

finger fails to detect any remaining strands of fibrous tissue. Bleeding is controlled by the silver nitrate stick and a vaselined wool pack. Control of postoperative pain by injection of an anesthetic in oil is not often used because the resulting fibrous may be detrimental. The important advantage of this procedure is the widening of the anal canal because of healing of the wound by ingrowth of epithelium instead of adhesion of its sides.

Reviewer's Note:

Three points should be emphasized regarding the pecten as agreed upon by those who have made a careful study of the anatomy of the anus.

1. The pecten is an area of subcutaneous fibrosis which may also involve the overlying skin.

2. It partially surrounds the skin but is not a complete band.

3. It is not constantly present with those lesions with which it does occur.

Wayne W. Flora, Chicago.

PETTIT, ROSWELL T., AND EDGCOMB, J. J.

Critical Analysis of Methods of Treatment of Rectal Carcinoma, Particularly Electrocoagulation. Am. Jour. Surg., XXXIV, 1:57-64, Oct., 1936.

The anatomy, pathology, diagnosis, and management of carcinoma of the rectum are briefly discussed, the management being classified under the following three methods: surgery, radiation, and electrocoagulation.

As a foundation for electrocoagulation therapy three factors are emphasized. First, the fact that carcinoma of the rectum is in most cases within reach of the finger makes it easily accessible for diagnosis and treatment. Second, carcinoma of the rectum metastasizes late. Wood and Wilkey are quoted as stating that spread is chiefly by local continuity and that spread by the blood stream is accidental. The authors state that these findings are in contrast to those of most pathologists who find widespread metastasis to lymphatics, peritoneum, and liver. Third, the five year survival following electrocoagulation compares favorably in the authors opinion with the 38 per cent to 50 per cent following surgery.

This writing covers their experience in the last nine years with 15 cases of carcinoma of the rectum treated by electrocoagulation, radium, X-ray or some combination of these. Colostomy was not used.

Electrocoagulation was used in 13 cases. Of these two were treated by electrocoagulation alone, six with radium and X-ray, three with radium, and two with X-ray. Of the two cases in which electrocoagulation was not used one was treated with radium and X-ray and the other which had been treated elsewhere with radium was treated with X-ray. Further analysis shows that of these 15 cases, two were treated by electrocoagulation alone, two by radiation alone, and 11 with electrocoagulation and radiation combined.

The most common complication following electrocoagulation is rectal stricture. There was one hemorrhage late in the second week and one death on the fifth day due to perforation and peritonitis.

Reviewer's Note:

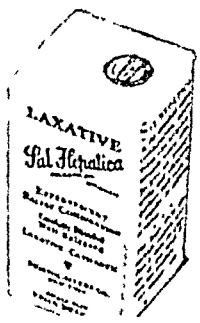
Electrocoagulation has been widely used in a number of conditions especially in the past few years. In a small series of cases in which radiation therapy has been used in addition to electrocoagulation, the beneficial results of the latter are difficult to evaluate satisfactorily. Up to the present time those surgeons who are generally considered as being best able to give a valuable opinion about therapy of carcinoma of the rectum by their extensive study and experience maintain that the malignant nature of the disease requires wide removal of the lesion and the lymphatic structures which might serve as a means of metastasis.

Wayne W. Flora, Chicago.

Salines

IN CONGENITAL CONSTIPATION

The regular use of salines is suggested in cases of constipation due to congenital hypoplasia of the intestinal musculature. The safety of the salines makes them particularly adaptable, as administration in such cases is usually prolonged.



Sal Hepatica

acts gently, yet thoroughly, in helping to rid the intestines of harmful waste by mild osmosis, diminished absorption and increased peristalsis. It provides natural mineral salts designed to conserve and replenish the body's alkaline stores . . . to help build resistance and promote general health improvement.

New experimental evidence indicates that Sal Hepatica stimulates an increased rate of bile flow from the liver into the gall bladder and thence into the duodenum.

The action of Sal Hepatica can be likened to that of well-known natural mineral spring waters. Its exuberant effervescence assures palatability . . . Samples and literature to physicians upon request.

Sal Hepatica Flushes the Intestinal Tract and Aids Nature to Combat Acidity

SECTION I—*Clinical Medicine: Diseases of Digestion*

The Effect of Administration of Aluminum Preparations on the Secretory Activity and Gastric Acidity of the Normal Stomach*

By
A. C. IVY, M.D., LAWRENCE TERRY, M.S.,
G. B. FAULEY, M.D.
and
WM. B. BRADLEY, M.S.
CHICAGO, ILLINOIS

ALTHOUGH aluminum preparations have been and are being used to some extent in the treatment of "peptic" ulcer in man (1, 2, 3, 4, 5, 6), we have been unable to find a study of the effect of the prolonged administration of relatively large quantities of such preparations on the secretory activity of the stomach of normal subjects. Einsel, Adams and Myers (2, 3) observed that the gastric acidity of ulcer patients was reduced after several weeks of treatment with aluminum hydroxide cream ("Al cream"), although a normal histamine response was obtained. Such a reduction in acidity may be ascribed to several factors, such as: (a) a natural decline of the "abnormally reacting" stomach in consequence of the remission of the ulcer; (b) a decrease in gastric retention as the ulcer enters a remission; (c) the aluminum, because of an astringent action on the gastro-intestinal mucosa, or the coagulation of mucin, or a reduction in gastric digestion, may decrease the secretagogic action of food; (d) the aluminum may cause a mild gastritis. The absorption of aluminum in systemic toxic amounts and an effect on the acid-base balance of the blood has apparently been ruled out (3). Because the possible operation of the first two factors one cannot derive from Einsel's observations what the real effect of aluminum medication on gastric secretion is. This work was primarily undertaken to answer that question.

METHODS

The investigation was conducted chiefly on healthy, vigorous dogs fed a balanced diet ad libitum. Two aluminum preparations were used. One was aluminum hydroxide cream. (In the earlier part of the work the cream was made by us; later we purchased Creamalin (Cleveland Chemical Associates), the buffering action of which was almost the same as our's). The other was Alucol, a colloidal aluminum hydroxide (Wander Co.) in the form of a powder, which was administered with a little water. A few experiments have also been performed on human subjects primarily for the purpose of ascertaining the degree of buffering of gastric acidity obtained with the aluminum preparations.

The capacity of the two preparations to buffer N/10 HCl was determined. Neither was immediately soluble in a large excess of N/10 HCl, Alucol being considerably less so than the Al cream, a factor that is concerned in the interpretation of our results. The samples of the preparations were set aside in contact with excess acid for periods of ½, 1, and 2 hrs., and then back-titrated with N/10 NaOH electrometrically. In order for one to check our results the details of our method of titrating must be given. Samples of 2 c.c. of the Al cream and 1 gram of Alucol powder were used. The samples were placed in 100 c.c. of N/10 at 37° C., the mixture being stirred about ¼ min. every 5 min. At the end of the periods stated, the samples were quickly cooled to room temperature (20° C.), 5 drops of 0.2% Töpfer's reagent were added and the mixture back-titrated with N/10 NaOH. Readings of alkali used were made at three different H-ion concentrations, namely, pH 3.76, or the first indication of change of Töpfer's from the red, at pH 4.0, and at the change of Töpfer's reagent to yellow, or a pH of 4.2. One c.c. of aluminum hydroxide cream buffered at a pH of 4.2, 9.21 c.c. of N/10 HCl in one-half hour, 10.34 c.c. in one hour, and 12.86 c.c. in two hours. One gram of the Alucol powder buffered at a pH of 4.2, 22.18 c.c. of N/10 HCl in one-half hour, 32.87 c.c. in one hour, and 34.97 c.c. in two hours.

The single doses of aluminum cream and Alucol actually used were 20 c.c. and 10 gm. respectively, such relatively large doses being chosen to obtain maximum effects, and to buffer theoretically from 250 to 350 c.c. of N/10 HCl in a two hour period, provided the acid and aluminum preparations were retained in the stomach, which of course, does not happen in vivo. In a one hour period these doses have the potentiality of buffering (pH 4.2) 206 c.c. and 328 c.c. of N/10 HCl respectively. The values for pH 4.2 only are given because we always titrated gastric samples to the yellow color of Töpfer's, an unmistakable end point.

To one group (5 dogs) 20 c.c. of aluminum cream, and to a second group (6 dogs), 10 gm. of Alucol were given four times a day, at 9 a.m. and at 1, 5, and 9 p.m. The dogs were fed at about 11 a.m., excepting on the days that test meals were fed. Medication was continued for more than four months.

Before starting the medication, an index of the secretion of the stomach was obtained (a) by feeding a test-meal and then aspirating a sample hourly for four hours, and also (b) by feeding the test meal three times per day and aspirating the stomach 4 hours after each meal, namely, at 1, 5, and 9 p.m. After starting medication the test meals and aspirations were performed about once weekly. The test meals were given with and without

*From the Department of Physiology and Pharmacology, Northwestern University Medical School, Chicago, Illinois.
Submitted October 29, 1936.

TABLE I

Animals on continuous medication for sixteen weeks

Averages, daily	Before Medication Control		After Medication First 9 weeks		After Medication Last 7 weeks	
	Free	Total	Free	Total	Free	Total
Aluminum Hydroxide Cream						
Plain Test Meals	.069	.220	.07	.23	.07	.20
Medicated Test Meals	.069	.220	.06	.19	.06	.21
Medicated Aspirations	.112	.240	.13	.28	.13	.25
Alucol						
Plain Test Meals	.077	.237	.11	.31	.11	.28
Medicated Test Meals	.077	.237	.05	.18	.07	.22
Medicated Aspirations	.131	.258	.14	.31	.16	.31

aluminum and the four hour aspirations were also made with and without the inclusion of aluminum.

The dose of aluminum was added to the meal; in the case of aluminum cream this was done throughout the period; in the case of Alucol, after several weeks the dogs would not eat their food with Alucol in it, so the Alucol was given by stomach tube, which did not influence the results because the dogs were habituated to taking the tube.

It should be pointed out that the aluminum preparations buffer alkali as well as acid. For this reason, although the values for free acid will be accurate, if much aluminum is present in the gastric sample the total acid value (phenolphthalein as an indicator) will be high. The nature of our results shows that the possible presence of aluminum in our gastric samples did not materially affect the total acid values. However, the greater significance is to be placed upon the free acid values. All titrations of gastric samples were made immediately.

RESULTS

The data are obviously very voluminous and cannot be given in entirety. The data, however, were sufficiently consistent to warrant the submission of averages for all dogs.

The averages on the five animals receiving 20 c.c. of aluminum cream 4 times daily for more than 4 months are shown in Table I. Similar data for Alucol are shown in Table I. The averaged acidity values of the non-medicated test meals before and after continued medication are shown as well as the medicated test meals before and after continued medication, and the four hour aspirations in which the meals had been medicated both before and after the continued period of medication. Such a scheme made it possible to determine the effect, if any, of long continued medication on the response of the stomach to non-medicated and medicated test meals. Any difference as much as ± 10% is significant.

It is obvious from an inspection of Table I that the administration of aluminum cream or Alucol in relatively large doses over a period of four months does not *decrease* the gastric secretory response to a test meal; no significant change occurred, the trend being toward a slight increase. In the case of Alucol and the plain test meals a definite increase occurred. This indicates that the stomach attempted to compensate for the buffering action of aluminum; and on the days that the non-medicated meal was given, the stomach continued to compensate as though aluminum had actually been added. This tendency to compensate is again shown in both the aluminum cream and Alucol data for the medicated aspirations, which were made 4 hours post-cibum, or at a time the stomach was practically free of food and medicament. As might be anticipated the acidity of the *medicated test meals* is reduced throughout the continued medication period, the reduction being greater for the first period of nine weeks than the latter seven weeks. This is not due to the stomach adapting itself to the aluminum after nine weeks or to the production of a gastritis, we believe, because when the average daily temperature meteorological curve is plotted alongside that of the gastric acidities, the decrease in acidities during the last seven weeks correlates with the average daily temperature, a fact that requires no discussion.

The attempt of the stomach to compensate for the effects of a neutralizing or buffering substance, of course, is a well-known phenomenon and occurs particularly in the case of alkalies (7). In the case of aluminum, however, the compensatory increase is not marked.

The effect of the addition of the aluminum preparations to a test meal. The same test meal employed in the former experiment was used and when medicated the same doses of the aluminum preparations given above were used. A gastric sample was obtained hourly for four hours.

Aluminum cream: Twenty-two animals were used. The non-medicated meal was fed 147 times and the medicated 137 times.

Alucol: The same experiment was conducted with Alucol on 28 animals. The non-medicated meal was fed 156 times and the medicated 117 times. The data are summarized in Table II.

First, it is to be noted that the data on the plain test meals in the two groups of animals (Table II) check remarkably, demonstrating the beauty of the averages of a large amount of data obtained under controlled conditions. The greater "buffering" effect obtained with Alucol in comparison to aluminum cream is due chiefly to the larger dose of Alucol administered, and we believe in part to the lower degree of solubility of Alucol. It is interesting that the ratio between the degree of lowering of free acidity at the 4 hour period in the case of aluminum cream and Alucol (0.028 : 0.038 = 74%) (Table II) is the same as the ratio between the "buffering" action of alumi-

num cream and Alucol in the doses used at a 2 hour period (257.2 : 349.7 = 74%). This means that the differences observed are due chiefly to the differences in dosages of the two preparations.

Aspirations four hours after feeding, or at 1, 5, and 9 p.m. were made on both groups of animals, with and without the meals being medicated. In the aluminum cream group 82 "non-medicated" and 146 "medicated" daily aspiration tests were made; in the Alucol group 124 and 183, respectively. The animals did not receive more than 2 medicated sets of meals per week. These data because of their bulkiness will not be submitted. They agree essentially with the results shown under the fourth hour period in Table II. In fact, we made the aspirations to check the four hour data in Table II, and to observe if any accumulative effect of the aluminum might be observed to occur when given once or twice weekly at four hour periods during the day. A slight accumulative or compensatory effect was observed on the days the aluminum was given, which did not manifest itself when plain test meals were given.

HUMAN SUBJECTS

It is obvious that the ingestion of either of the two aluminum preparations will buffer gastric acid. However, we desired to perform a few experiments on several human subjects to ascertain how effective they might be.

Alcohol test meals: The normal gastric response of 6 graduate students, accustomed to the stomach tube, to 50 c.c. of 7% alcohol, after evacuating the gastric residuum, was determined. Then, the alcohol test was performed with Alucol (1.4 gm.) or Creamalin (4 c.c.), which was taken immediately after the alcohol. The curves (free acid only) of the average response of the group for two hours shows that the aluminum preparation reduced the free acidity for 45 minutes or longer. The variation in the response from subject to subject was rather marked, and the tendency to an increase in acidity after the aluminum had been evacuated, was characteristic of 4 of the 6 subjects.

Regular meals: The subjects (6 graduate students) in these experiments were instructed to choose a breakfast, a lunch and dinner and to ingest the same meals on three successive days, hourly samples of the gastric contents being withdrawn and titrated immediately. One day served as a control, and during the other two days either Alucol (1.4 gm.) or Creamalin (4 c.c.) were taken ½ hour after each meal and again at 10 a.m. and 3 and 8 p.m. The curves (free acid only) of the group averages show that the free acidity is reduced, but tends to rise to normal values an hour before the next meal. (It should be kept in mind that 4 c.c. of Creamalin and 1.4 gm. of Alucol buffer only about 40 c.c. of N/10 HCl in the test tube).

Similar experiments were performed in 10 subjects (students) except that the dose of the aluminum preparations was increased slightly and given hourly on the half hour for 14 hours. The subjects ate at 7 a.m., 12 noon, 6 p.m., and hourly at the half-hour they took 5 c.c. of aluminum cream (buffers 51.7 c.c. N/10 HCl in 1 hour and 46 c.c. in 0.5 hour) until 8:30 p.m. A gastric sample was removed on the hour and just before eating the noon and evening meal. A similar series of tests was made using 1.6 gm. of Alucol (buffers 52.6 c.c. N/10 HCl in 1 hour and 35.5 c.c. in 0.5 hour). Chart 1 shows the group averages and the results of subject Gr., whose free acid was reduced least of all. (The aluminum preparations tend to cause constipation in some normal subjects).

Effect of continuous and prolonged administration of aluminum hydroxide preparations on blood chlorides and plasma CO_2 combining power. The plasma CO_2 combining power and total blood chloride level were studied in eight dogs, four receiving 20 c.c. of aluminum cream and four 10 gm. of Alucol four times daily at 9 a.m., 1, 5, and 9 p.m. The plasma CO_2 combining power was found to be in the normal range for dogs, 46 and 56, average 49, volumes per cent. The blood chlorides expressed as sodium chloride ranged from 3.83 to 4.62, average 4.31 grams per liter which is slightly below or in the lower limits of the normal.

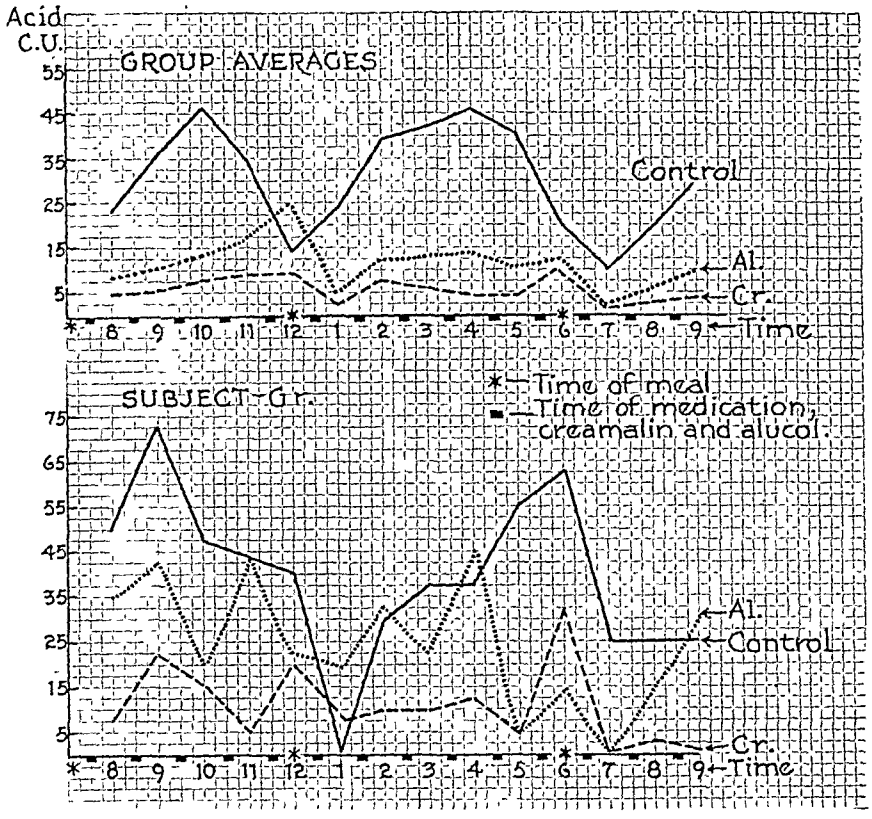

Chart 1

This confirms the findings of Einsel and others (2, 3) with the exception that our chloride values are somewhat lower, but our doses were relatively larger. The chloride values on patients receiving aluminum cream also fell in the lower limits of the normal range.

DISCUSSION

In view of the astringent action of aluminum hydroxide we rather anticipated a decrease in the gastric secretory response to a meal. No evidence showing that such occurs on the single or continued daily administration of the two preparations was obtained. The buffering action on the acidity of the gastric contents observed was of course to be expected and no significant difference in the two preparations in this regard was noted. It has been shown clearly by Boyd (7), using Pavlov pouch dogs, that alkalies such as sodium bicarbonate and calcium carbonate in ordinary doses given over a long period of time do not depress gastric secretion. Very large doses (3 gm. per kilo) depress, and on their withdrawal, a hypersecretion occurs. Small doses tend to augment secretion. No evidence was obtained indicating that the doses of the aluminum preparations used, given intermittently, stimulate secretion. However, the protracted administration of the preparations tended to augment secretion to non-medicated test meals given on days when medication was dithdrawn. This tendency of the stomach to compensate is analogous to that observed by Boyd in the case of alkalies, and in our experiment it cannot be ascribed to changes in acid base balance in the blood, since significant changes do not occur (2).

On the basis of our results pertaining to the amount of "buffering" of acid that occurred after the administration of the aluminum preparations, we doubt, as Einsel does, that the antacid properties of aluminum hydroxide preparations in the doses usually employed fully explain its reported effectiveness in "peptic" ulcer. In animals that have received the aluminum preparations for some time, one finds at autopsy the folds of mucosa in the stomach and duodenum covered with flaky curds, presumably precipitated mucin. Sometimes the duodenum is so coated that about two-thirds of its mucosa appears as if it had been covered with flour paste. This has been reported by numerous observers.

We chose the relatively large doses of the two aluminum preparations to administer to the dogs (a) because we doubted that one would desire to administer much larger daily doses to man, and never a larger per kilo dose, and (b) because we were interested in making observations on toxicity.

The question of the *toxicity of aluminum compounds* has been investigated and discussed pro and con at considerable length. The older literature has been reviewed by Smith (8). Unfortunately, much of the older work was not accompanied by histologic studies and the methods for the chemical analysis of tissue were not sufficiently sensitive and specific to render the results of value. Since 1929, however, more accurate methods (9-14a) for quantitating aluminum in biological materials have become available, the colorimetric method of Eveleth and Myers being the most suitable. It now appears established that rats may

be fed diets containing from 0.6 to 2.6 per cent aluminum chloride or other soluble aluminum salts for a year without producing histologic changes in their organs, affecting growth, producing anemia, or affecting reproduction (18-22). The only meager reports to the contrary (23) are incomplete. Aluminum compounds injected intravenously or subcutaneously in adequate doses are toxic, producing focal necrosis and swelling in the liver and kidney principally (11). So in the case of injection of aluminum, apart from the local irritating action of soluble aluminum compounds, the important question in regard to toxicity is how much aluminum is absorbed. Two studies (9a, 19) indicate that when soluble aluminum salts are perfused through an intestinal loop significant quantities are not absorbed, it being suggested that due to the alkaline reaction the colloidal hydroxide would be formed which one should hardly expect to be absorbed in appreciable quantities. When the more soluble compounds have been fed by mouth to rats and dogs in the amounts stated above, two investigations (13, 24) report no detectable absorption, four (14, 19, 11, 25) slight absorption, and two (23, 21) absorption in toxic amounts. As several investigators point out, the latter two investigations are open to criticism and could not be confirmed. Considering the results as a whole, it would appear that aluminum chloride, lactate and citrate, aluminum sulphate, when given in 2% per cent diets orally, results in a slight increase in the aluminum content of tissues. Only traces appear in the organs of the maximum normal are obtained. All results so far obtained indicate that chronic administration does not lead to a storage or a cumulative deposition of aluminum in the liver and kidney. Aluminum compounds of course are toxic (26). But, in rats placed on a diet to cause a nutritional anemia, aluminum was found to exert no effect (27), as in rats on a normal diet, conflicting results have been reported (2a, 18a). The German Bureau of Health (27a) fed dogs aluminum sulphate in quantities corresponding with 1 gm. of aluminum oxide (Al_2O_3) daily for a period of 8½ months. No change in the appetite or body weight occurred, and no harmful or change in the organs of the animals was observed. The aluminum content of the organs was within the normal range. A similar dose was given to man without causing symptoms. Traces of aluminum were present in the urine but a significant increase was not observed (12, 2 3a).

In our normal animals no significant changes in appetite and body weight have occurred with the relatively large doses of colloidal aluminum administered. However, we are interested in ascertaining the results of aluminum medication to Mann-Williamson dogs in which a tendency to hypersecretion of gastric juice exists along with a deficiency of alkaline pancreatic juice and bile to convert any aluminum chloride formed in the stomach to the insoluble hydroxide. To date our data for aluminum in the liver of such medicated dogs, receiving aluminum for from 3 to 8 months, have fallen in the normal range, except in one dog with a very fatty liver (aluminum, 0.14 mg. per gm. of dried liver). Underhill (11) found his highest hepatic content of aluminum in the liver of a man whose liver was fatty. Our complete data on this question will be reported when our results on Mann-Williamson dogs are completed.

CONCLUSIONS

1. When aluminum preparations (aluminum hydroxide cream and powdered colloid aluminum hydroxide powders in relatively large daily doses, larger than recommended in the therapy of "peptic" ulcer in man, are administered for a period of 4 months to normal dogs, a decrease in the gastric secretory response to a meal does not result. The decrease in acidity reported to occur in ulcer patients on aluminum therapy must be due to other factors than the effect of the aluminum directly on the gastric secretory mechanism. Under prolonged aluminum administration the gastric secretory mechanism tends to compensate for the buffering action of aluminum, or to respond to other possible effects of aluminum, since we observed slightly higher acid values for the gastric contents when non-medicated test meals were used. The failure to observe this effect in human patients (2) may be due to the smaller doses employed clinically.

2. When aluminum preparations are administered with a meal in a relatively large dose once or twice weekly, no definite change in the gastric secretory response to a meal is observed. Temporary "buffering" of acidity is of course obtained.

3. The health of the animals was not impaired, as judged by the outward appearances, in spite of the relatively large doses of aluminum. The aluminum content of the liver of seven of eight dogs receiving the aluminum for a period of from three to eight months was within the normal range of variation. A review of the literature pertaining to the question of the toxicity of aluminum compounds is presented.

4. The effects of administering aluminum preparations, both hourly and six times a day, on the free acidity of the gastric contents in normal human subjects eating three meals a day are reported. As might be anticipated, the aluminum preparations buffer free acid and are more effective in this regard when administered more frequently.

Lymphosarcoma of the Stomach*

A Study of Four Cases

By

E. N. COLLINS, M.D.

and

M. G. CARMODY, M.D.

CLEVELAND, OHIO

ALTHOUGH sarcomata of the stomach comprise only about one per cent of all gastric neoplasms, a surprising number of cases is reported in the literature. In studying these reports, one is impressed with the difficulties which attended the clinical and roentgenological diagnosis of this condition and *also with the fact that an early diagnosis is even more* important in sarcoma than in carcinoma, at least from the standpoints of operability and curability.

Undoubtedly, the fact that sarcomata seldom involve the gastric mucosa early and therefore produce no characteristic deformity of the stomach on roentgen examination has led in many instances to the erroneous conclusion that no neoplasm was present, in spite of the clinical evidence. In such cases the possibility of sarcoma and its different pathological process from that found in carcinoma should be considered.

Our experience with a group of four proved cases of lymphosarcoma of the stomach will be discussed. Two of these, cases 1 and 4, have been reported previously (1, 2).

Case 1: A man, 55 years of age, complained of epigastric distress, characterized by a dull pain which came on immediately after eating. He had lost 20 pounds in weight. A roentgen examination made when his illness began (five months prior to admission) was reported as showing evidence of an ulcer on the lesser curvature of the stomach. The patient was given 24 daily intramuscular injections of a four per cent solution of l-hystidine monohydrochloride (Larostidin); this was followed by symptomatic relief for four months but the epigastric distress recurred, and another series of injections gave no relief.

The patient entered this Clinic and an abdominal examination revealed a large incisional hernia medial to the upper right rectus scar which followed previous cholecystectomy, but no palpable mass was present. Examinations of the blood gave normal findings. The night after his physical examination the patient had a gastric hemorrhage and entered the hospital. He was placed on strict ulcer management. Symptomatic relief lasted for two weeks but the epigastric discomfort returned and included night distress at 2 a. m. An Ewald meal at this time revealed an absence of free hydrochloric acid.

Roentgen examination was then made and the stomach would have appeared normal had there not been a careful study of the gastric rugae after the ingestion of a small amount of barium suspension. This procedure revealed an irregular ulceration on the posterior wall of the stomach, but it was not apparent when the stomach was completely distended with barium (Fig. 1). A diagnosis of an ulcerating neoplasm was made.

At operation, a large ulcerating lesion was found on the posterior wall of the pars media of the stomach; this process extended nearly to the cardiac orifice. The lesion was thought to be carcinomatous, and since no glandular involvement could be discovered a total gastrectomy was performed by Dr. T. E. Jones.

Examination of the stomach after removal revealed an indurated mass on the posterior wall just below the lesser curvature. On opening the stomach, a large indurated ulcer was found which measured 9 cm. longitudinally and 7.5 cm. transversely and extended from the cardiac opening toward the pylorus (Fig. 2). Microscopical examination showed it to be a diffusely infiltrating lymphosarcomatous growth involving all coats of the stomach (Fig. 3). Sections of three lymph nodes from the lesser omentum showed no evidence of metastasis.

Comment: This patient emphasizes (1) the necessity for a careful study of the rugae in all gastric roentgen examinations, and (2) the intermittent symptomatic relief which may occur in the presence of lymphosarcoma.

Case 2: This patient, a woman aged 55 years, entered this Clinic complaining of epigastric distress of a gnawing character. This was not relieved by food or soda and had been present for three weeks. Two weeks prior to entrance, she vomited a small amount of brownish material and the stools became dark in color.

Examination of the abdomen revealed a firm, rounded, smooth, and slightly tender mass, the size of a baseball, below the right costal border just inside the right mammary line. It moved with respiration and the liver could not be palpated.

Examination of the blood showed 3,010,000 red cells, 8,000 white cells, and 61 per cent hemoglobin. The blood Wassermann and Kahn reactions were negative. The Ewald test meal revealed an absence of free hydrochloric acid.

During the *roentgen examination*, the palpable mass was found to be outside the lumena of both the stomach and colon. It was movable and lay between the pyloric end of the stomach and the hepatic flexure of the colon, compressing both. The duodenum was not well visualized; by exclusion the mass was thought to be either in the duodenum or related thereto. The rugae in the pyloric third of the stomach were not well visualized but this was thought to be due to the extrinsic pressure of the mass (Fig. 4).

At operation, the mass was found to arise in the region of the pylorus of the stomach. Although the growth appeared to be extrinsic, it was considered an atypical variety of carcinoma, and partial gastric resection was done.

Excerpts from the *pathological report* are as follows: "The anterior surface of the stomach is smooth and glistening, but just proximal to the pyloric ring there is a bulging, smooth, regular protuberance, measuring 6 cm. in length and 4.5 cm. transversely. The posterior surface is roughened and irregular and has numerous fibrous adhesions over it. On opening the stomach, there is an ulcerated area which extends over the entire posterior wall and over the greater portion of the anterior wall, almost

*From the Cleveland Clinic.
Submitted August 24, 1936.

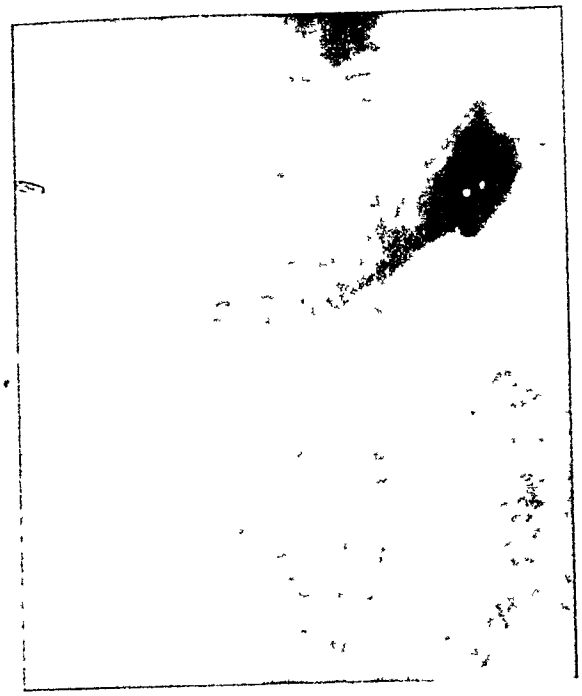

Fig. 1, Case 1. Roentgenogram showing evidence of an ulcerating neoplasm. When the stomach was completely filled with barium suspension, no evidence of abnormality was apparent.

completely encircling the stomach, except for a narrow strip on the lesser curvature" (Fig. 5). After microscopical examination, the pathological diagnosis was "lymphosarcoma, stomach and gastric lymph nodes" (Fig. 6).

The patient made an uneventful recovery from the operation and before leaving the hospital was given a course of deep roentgenotherapy to the upper abdomen and mediastinum. Later, metastases developed in the cervical lymph nodes and in the region of the right kidney. Roentgenotherapy was administered to both these areas, and even though there was a complete disappearance of all palpable nodes, death occurred seven months subsequent to operation.

Comment: In this patient, if the roentgenologist had interpreted his findings correctly the preoperative diagnosis should have been sarcoma. If more attention had been given to the gastric rugae and less attention to the feature of extrinsic pressure, the extensive shallow ulceration which nearly encircled the pyloric third of the stomach in association with an extra-lumenal mass would have been obvious.

Case 3: This patient, a man 68 years of age, complained of weakness and the loss of 37 pounds in weight during the preceding year. Approximately one year prior to entrance, he began to have indefinite pains in the abdomen, usually immediately after eating, and a diagnosis of "colitis" was made. He steadily grew weaker and lost weight but his abdominal distress subsided. Then a heavy feeling in the epigastrium developed. Six weeks prior to entrance, a roentgen examination was reported as showing no abnormality of the stomach.

Abdominal examination revealed no palpable organs or masses. Examination of the blood showed 2,640,000 red cells, 17,700 white cells and 45 per cent hemoglobin. Blood Wassermann and Kahn reactions were negative. The urine showed an occasional hyaline cast. The Ewald test meal revealed an absence of free hydrochloric acid. Examination of the stools was positive for blood.

Roentgen examination revealed an extensive neoplasm involving the proximal half of the stomach, particularly the lesser curvature where there was a large ulcer associated with evidence of considerable infiltration in the wall of the stomach.

The patient died thirteen days after admission. *At autopsy* the entire cardiac end of the stomach was made up of a pale, opaque, spongy, friable tumor. The tumor mass terminated about 5 cm. proximal to the pyloric sphincter on the lesser curvature. In the middle of the tumor area, there was a complete loss of gastric tissue, the tumor having extended into the liver, and the latter formed the anterior gastric wall in this area. Another ulcerated area in the cardiac end of the stomach was in continuity with the spleen.

The microscopical diagnosis was "lymphosarcoma of the stomach with extension into the left lobe of the liver, diaphragm, omentum, and mesentery, and metastases to the epicardium, mesenteric nodes, and ureter."

Comment: This patient illustrates extensive involvement of the mucosa late in the course of the disease. Apparently, the involvement occurred shortly before death because a roentgen examination was reported as showing no abnormality six weeks prior to entrance.

Case 4: A white boy, nine years of age, was admitted to St. Vincent's Charity Hospital in 1914, complaining of abdominal pain, nausea and vomiting which had been present for two months. His symptoms were those of an aching epigastric discomfort which began one year previously when he was struck in the "pit of the stomach" with a baseball.

Examination revealed emaciation and a tender tumor mass in the epigastrium. A clinical diagnosis of sarcoma of the stomach was made by Dr. F. E. Bunts and at operation, he found a large mass which involved the pyloric third of the stomach with glandular involvement of the greater curvature. A partial gastrectomy and a posterior gastro-enterostomy were performed in 1914. The patient made an uneventful operative recovery.

The surgical specimen weighed over 900 grams and a pathological diagnosis of lymphosarcoma of the stomach

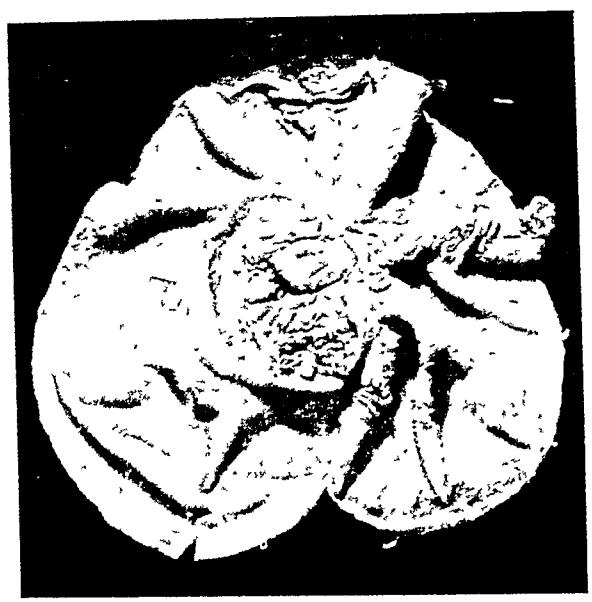

Fig. 2, Case 1. Photograph of gross specimen showing a large, indurated ulcer.

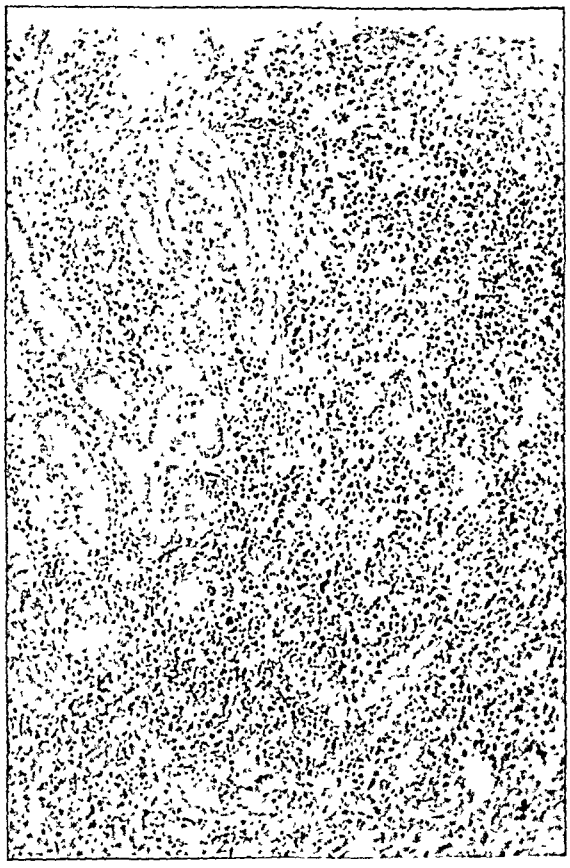

Fig. 3, Case 1. Photomicrograph showing a diffusely infiltrating lymphosarcoma (x 150).

was made. The patient is living and well today—twenty-two years after operation—with no evidence of recurrence.

INCIDENCE

Considerable interest in the subject of sarcoma of the stomach is evident from the amount of literature available. One of the most recent comprehensive reviews is that of Pack and McNeer (3) who cite the incidence as 1 per cent of malignant gastric tumors. In all cases of proven malignancy of the stomach at the Cleveland Clinic, the incidence of sarcoma is 0.7 per cent. The average age of our patients was 47 years, the youngest patient was 10 years of age and the oldest 68 years. It will be noted that this average age compares closely with that reported by other authors. The age incidence for sarcoma has been reported by some authors to be from five to twenty years below that of carcinoma, but Crohn (4) states that the greater number of cases occur in the fifth and sixth decades.

ETIOLOGY

The etiology of this, as of all malignant tumors, remains obscure. In Case 4 the patient dated the onset of his symptoms from the time he was struck in the "pit of the stomach" by a baseball. McWhorter (5) and others have pointed out that trauma may play a definite *rôle*. Kimpton (6), Warner (7), and Kapel (8) have reported cases in which the growth had existed for years and then underwent malignant change, and these writers feel that it is possible for a sarcoma to become engrafted upon a leiomyoma of the stomach just as such a process takes place in a leiomyoma of the uterus. Evidence has been presented to show that inflammation, irritation, preexisting neoplasms, chronic ulcers, and tuberculosis may be causative factors in the production of this type of tumor, but this has not been proved conclusively.

PATHOLOGICAL FEATURES

Gastric lymphosarcomata originate from the lymphoid follicles of the submucosa which form solid or cystic growths or a diffuse, infiltrating process. Finally they project either into the lumen of the stomach or outward under the peritoneum, more often the latter.

Most pathologists agree with Schlesinger (9) who classified sarcoma of the stomach into three types: First, the exogastric; second, the submucosal or possible intragastric; and third, the gross sarcomatous infiltrating type. The exogastric type, which arises in the subserous connective tissue layer, spreads between the layers of the gastrohepatic or gastrocolic omentum and may involve very little of the stomach wall. Unlike carcinoma, the line of demarcation between the tumor and normal stomach is usually well defined and sharply outlined. The other two varieties have the characteristics of lymphosarcoma as mentioned above.

Ewing (10) has divided sarcoma of the stomach into three distinct histological groups: the spindle cell myosarcomata, which usually constitute the exogastric type of growth; the lymphomatous tumors, which include the lymphosarcomata, and the miscellaneous

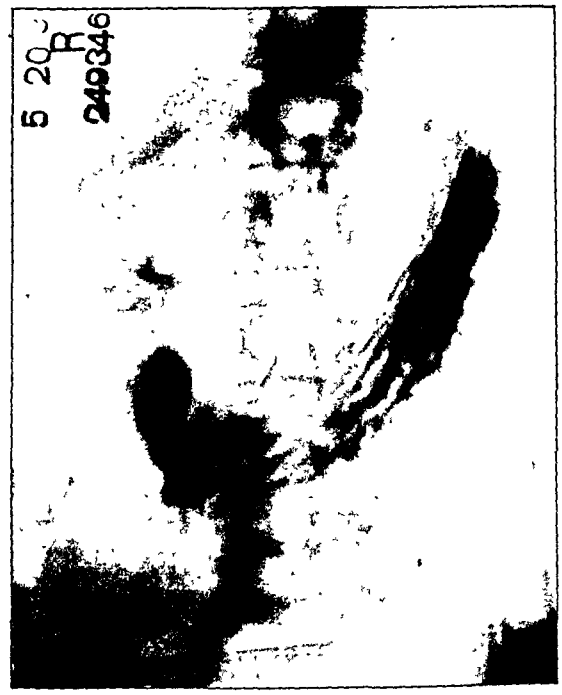

Fig. 4, Case 2. Roentgenogram of stomach made after the ingestion of a small amount of barium suspension. (I) Soft tissue mass in anterior wall of stomach (outside of gastric lumen). (II) The line of demarcation below which there was extensive ulceration almost completely encircling the pyloric third of the stomach.

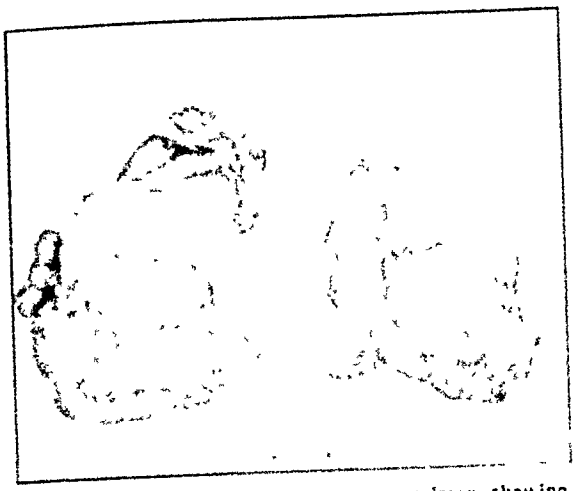

Fig. 5, Case 2. Photograph of gross specimen showing tumor in anterior wall of stomach and extensive shallow ulceration

round cell and alveolar types of sarcomata in which the structure does not appear to fall into any one of the common groups.

Unlike carcinoma, the mucous membrane in sarcoma is not involved until late in the course of the disease. When ulceration is present, it is usually due to a necrosis resulting from pressure or to the loss of blood supply rather than to neoplastic invasion. Thus, a large segment of mucous membrane may slough, leaving an extensive shallow ulcer as in Case 2. It appears probable that a sarcoma of the stomach may exist for months without involvement of the mucous membrane and finally an extensive slough may occur quite suddenly.

CLINICAL FEATURES

The exogastric variety of sarcoma, which usually produces a palpable mass, may be mistaken for retroperitoneal tumor, pancreatic or mesenteric cyst, and because splenomegaly is present in 10 per cent of cases of sarcoma of the stomach, Banti's disease also may be confused with this condition. In some of the reported cases of other varieties, the symptomatology was that of a benign peptic ulcer. Usually, soon or late the symptoms and signs of all sarcomata of the stomach are similar to those of carcinoma. In addition to epigastric distress, the patient generally complains of weakness and loss of weight. Secondary anemia and achlorhydria are common findings, as were present in three of our cases. Obstructive symptoms are rarely present because sarcoma is not prone to involve the orifices of the stomach.

The duration of symptoms may be longer than is the case in carcinoma. In a series of fifty-four cases reported by Balfour and McCann (11), the average duration of symptoms was more than a year; there was evidence of bleeding in sixteen and of a palpable tumor in over half the cases. In our patients, the average duration of symptoms was seven months, the shortest being three weeks and the longest one year.

ROENTGEN EXAMINATION

In view of the pathological features mentioned, the diagnostic reliability of the roentgen examination in sarcoma of the stomach cannot be so great as it is in other types of neoplasm or ulcerating processes which primarily involve the mucosa. The pathological process may be limited to the stomach wall without any involvement of the mucosa and there may be little if any disturbance in the peristaltic activity of the stomach. If a palpable mass is present, the roentgenologist may believe it has no connection with the stomach when there is no encroachment upon the gastric lumen (Case 2). On the other hand, there may be ulceration, the character and extent of which are entirely different from such usually encountered in other types of ulcerating process (Cases 2 and 3) (12). The routine mucosal relief methods of examining the gastric rugae are unusually important in sarcoma because the ulceration, if present, may be shallow (13). Cases have been reported wherein the gastric rugae were decidedly enlarged, suggesting a marked submucosal infiltration, but this finding alone makes impossible a differentiation between a hypertrophic gastritis, a submucosal infiltrating carcinoma, or an infiltrating lymphosarcoma (11). Too much emphasis cannot be placed on the fact that a roentgen examination may show no abnormality at one time but reexamination within a few weeks may show evidence of extensive ulceration (Case 3).

DIAGNOSIS

Strauss (15) and Haggard (16) have emphasized that the presence of hematemesis with melena in a young person and a palpable epigastric tumor without

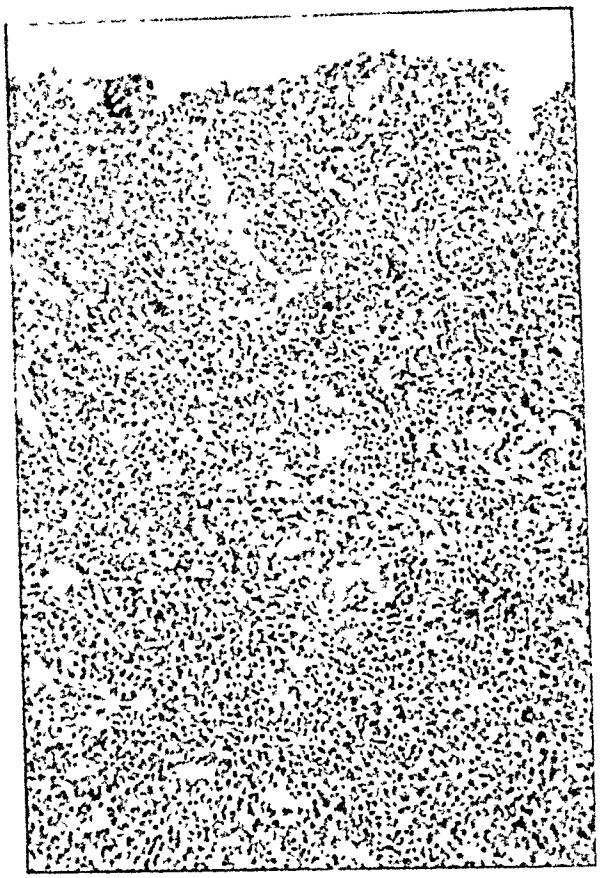

Fig. 6, Case 2. Photomicrograph showing lymphosarcomatous growth (x 150).

obstruction are suggestive of the presence of sarcoma of the stomach. A clinical diagnosis is seldom made preoperatively. However, we believe this lesion should be suspected in any patient, regardless of age, who has had continuous gastric symptoms and signs suggesting a neoplasm for a few months, a year or more, when the roentgenologist finds either no evidence of mucosal involvement or evidence of a large shallow ulceration which is not characteristic of either benign peptic ulcer or ulcerating carcinoma, especially if associated with an extralumenal mass. A sarcomatous mass which involves the lumen of the stomach obviously cannot be differentiated roentgenologically from other types of neoplasm. Renshaw (14) has recently reported a case of lymphoblastoma of the stomach with especial reference to the gastroscopic appearance.

TREATMENT

The operability of sarcomata of the stomach is greater than that of carcinomata. When the diagnosis *is established, resection of the growth is the procedure* of choice. Of the fifty-four cases in Balfour and McCann's series (11), thirty-eight were operable. At the time of their report, death had occurred in twenty-six. The average duration of life in those who died was eleven months and in those still living, it was five years.

If resection is not possible, palliative surgical measures may be employed. Pack and McNeer (3) state that all sarcomata of the stomach, except the spindle cell variety, are radiosensitive tumors. If the lesion is a lymphosarcoma, radiation therapy is especially indicated.

Pattison (17) has reported a case of diffuse lymphosarcomatous infiltration of the stomach on which a biopsy was made, and in which roentgenotherapy was the sole method of treatment. The patient was a boy of twenty years to whom repeated courses of deep roentgenotherapy were given. At the time of the report, fifteen months after the operation, the patient was in perfect health and had gained twenty pounds.

When there is roentgen evidence of neoplastic involvement of the cardiac end of the stomach and operation is not performed, the possibility of using a course of roentgenotherapy as a diagnostic procedure should be considered. If "progress" roentgen examinations show definite improvement, further roentgenotherapy would be indicated, conceivably on the basis of a radiosensitive sarcoma.

PROGNOSIS

The prognosis in sarcoma of the stomach, of course, varies with the character and duration of the lesion, the presence or absence of metastases, and whether or not it is operable or radiosensitive. It is unusual for these patients to survive for more than three to five years, because metastases are often present at the time of operation or initial roentgenotherapy. Earlier diagnoses may be made in the future. According to D'Aunoy and Zoeller (18), most authorities agree that the pedunculated growths, which usually are the spindle cell type, offer a better prognosis as compared with the infiltrating varieties which are most frequently lymphosarcoma or round cell in type. The reasons which they give are that those of the spindle cell type grow more slowly, have a tendency to remain circumscribed, do not metastasize so early, and are removable. However, in a review of the literature we have found that patients with lymphosarcoma comprise the greatest number of those surviving over a five-year period.

SUMMARY

1. The diagnostic difficulties encountered in four proven cases of lymphosarcoma of the stomach are reviewed.

2. The roentgen examination of the stomach may show no evidence of abnormality until late in the course of the disease inasmuch as the mucosa may not be involved prior to that time.

3. Two cases of lymphosarcoma are added to the literature.

4. In dealing with an obscure diagnostic problem involving the stomach, the rare possibility of sarcoma and its different pathological progress from that found in carcinoma should be considered.

Intravenous Galactose Liver Function Test*

By

I. R. JANKELSON, M.D., M. SEGAL, M.D.

and

M. AISNER, M.D.

BOSTON, MASSACHUSETTS

IN a previous communication by one of us (1) the intravenous and oral galactose liver function tests were discussed. In the oral method there are at least two possible sources of error, which materially influence the sensitiveness of the test. The first is the intestinal rate of absorption. The second is a renal factor; the excretion of galactose may be influenced by a possible renal threshold value (2) or by renal disease. Both of these factors are eliminated in the intravenous test. On the other hand, the complicated chemical procedures and the multiple venipunctures constitute disadvantages and limitations to the practical applicability of the intravenous galactose liver function test. These, however, are of a degree comparable with other accepted tests like the glucose tolerance test and can be conducted by any well equipped clinical laboratory.

It is believed that galactose is metabolized by the liver only. Hence, any delay or diminution in the utilization of the galactose can be referred to a diminished liver function. A normal liver can metabolize within one hour, 25 gms. of intravenously injected galactose. Thus, any demonstrable galactose in the venous blood, one hour or longer after the injection of 25 gms. of galactose implies liver pathology. The rate of utilization can be studied by repeated observations at intervals of 15 minutes beginning one hour after the injection. The greater the retention of galactose, the greater the liver damage.

TECHNIQUE

Further observations with this test lead to some modifications of the technique. Instead of a 50 per cent, we are now using a 25 per cent solution of galactose. In this way, the viscosity of the solution is diminished and caramelization after autoclaving prevented. To avoid annoying reactions, characterized by chills and tremors, a buffer is added to the sterilized galactose solution. We have eliminated the analysis 30 minutes after galactose injection as of no practical value. On the other hand, a blood sample 75 minutes after the injection of the galactose solution proved of interest.

The present technique is as follows: A fasting venous blood sample is taken and oxalated in the usual way. Through the same needle 100 c.c. of a properly warmed, sterilized and buffered 25 per cent galactose solution, is injected slowly intravenously. Venous blood samples are taken and oxalated 60, 75 and 90 minutes later. The patient remains throughout this period in a fasting state.

From each of the four blood samples a Folin and Wu tungstic acid filtrate is prepared. The fermentable reducing substance is fermented out by the technique of Somogyi (3). The amount of non-fermentable reducing substance is determined by the method of Folin and Wu. The difference between the non-fermentable reducing substance in the first blood sample and in the blood samples following the injection of galactose, divided by 0.75 for the difference between glucose and galactose reduction, represents the galactose retained within the venous blood.

OBSERVATIONS

We have studied the rate of galactose utilization in five groups of patients: (1) Patients without demonstrable liver or biliary tract disease; (2) Patients with intrahepatic jaundice; (3) Patients with obstructive jaundice; (4) Patients with cirrhosis of the liver; (5) Patients with gall bladder disease.

(1) *The patients without liver or biliary tract disease* have all shown complete utilization within one hour of 25 gms. of intravenously injected galactose. Thus, the standard of normalcy has been established and our previous observations confirmed on a much larger group of cases. Included in this group are people without any demonstrable disease as well as patients with a great variety of pathological changes but without obvious liver pathology.

(2) *In patients with hepatitis*, whether toxic or infectious, retention of intravenously injected galactose one hour or longer is found in all cases except in subsiding catarrhal jaundice, when the galactose test may be negative. In a general way, the highest degree of galactose retention occurs at the height of the disease. The galactose retention drops rapidly as recovery from the liver damage ensues. There is no obvious relationship between the height of jaundice as determined by the icteric index or the Van den-Bergh test, and the degree of galactose retention. The latter diminishes or may become normal before the jaundice clears. The amount of galactose retention depends, on one hand, upon the amount of liver cell degeneration and, on the other hand, upon the amount of cell regeneration. Therefore, it varies from case to case and in the various stages of an individual case.

The curves of galactose retention in these cases vary a great deal. We have observed variations of 2.3 to 13.3 mgs. of galactose per 100 c.c. of blood plasma 60 minutes after the intravenous injection of galactose. Similar variations occur in the 75 and 90 minutes blood samples in which the galactose values varied from 0 to 10.1 and 0 to 2.6 mgs. per 100 c.c. of blood plasma respectively. The mean curve of 10 cases studied is shown on Chart I.

(3) Six *cases of obstructive jaundice* were studied with the intravenous galactose liver function test. Four of these cases had a carcinoma of the head of the pancreas and two a common bile duct stone. Two cases of carcinoma of the head of the pancreas and one case of common duct stone with obstruction gave

Minutes after injection.
——— curve in cirrhosis of liver ..... curve in hepatitis
oooooo curve in obstructive jaundice.

positive galactose tests. Thus, 50 per cent of the obstructive jaundice cases had some galactose retention one hour after an intravenous injection of the standard amount of galactose. The mean curve in the three cases is shown on Chart I. It can be seen from the chart that the greatest variation between the two types of jaundice occurs at 75 minutes. In obstructive jaundice there are only traces (0.70 mgs. per 100 c.c.) while in intra-hepatic jaundice 2.7 mgs. is found in the blood plasma. Both at 60 and 90 minutes the galactose retention in both groups is practically the same. It would appear that the factor, which determines whether galactose is retained or not, is the duration of the obstruction and not the degree of jaundice. In the cases with a positive test the jaundice was distinctly of longer duration than in the negative ones. This should be interpreted as a secondary hepatitis or biliary cirrhosis from a long-standing obstruction.

(4) Twenty-five cases of *portal cirrhosis* were studied with the intravenous galactose liver function test. In this group 16 patients (64 per cent) gave a positive, while 9 (36 per cent) gave a negative test. The mean curve of the 16 positive cases is shown in Chart I. The galactose values were as follows: At the end of one hour (9.42 mgs. per 100 c.c.) at 75 minutes (3.33 mgs. per 100 c.c.) and at 90 minutes (0.96 mgs. per 100 c.c.). The degree of retention is higher than in the two previous groups. In individual cases the amount of galactose in the venous blood varied at 60 minutes from 2.7 to 22.4 mgs., at 75 minutes from 0 to 13.3 mgs. and at 90 minutes from 0 to 10.4 mgs. As these figures show, there is a great deal of variation in these cases. We were, however, unable to correlate the retained galactose with jaundice or size of the liver. In all cases of portal cirrhosis with ascites galactose retention was present.

(5) All cases of *cholecystitis*, with or without stones in the absence of obstruction to the biliary tract, metabolized 25 gms. of intravenously injected galactose within one hour. Several cases had a mild transient jaundice. As has been mentioned before, one of the two cases of cholelithiasis with common duct obstruction gave a positive intravenous galactose liver function test.

DISCUSSION

Positive intravenous galactose tests indicate liver damage. On the other hand, negative tests do not rule out liver disease. At no time did we find galactose retention at the end of an hour in patients without demonstrable liver or bile duct disease. Gall bladder disease without common bile duct obstruction gives a negative intravenous galactose liver function test. Intrahepatic jaundice cases show a definite retention of galactose which is demonstrable in all cases, except in the stage of recovery. In obstructive jaundice, retention of galactose may be absent or present. If present, the amount of galactose retention seems to depend upon the duration of biliary obstruction. Therefore, if this test is to be used in the differential diagnosis between intrahepatic and obstructive jaundice, it must be performed in the early stages of the disease. When so done, a positive test indicates intrahepatic jaundice. When the disease is of long standing, intrahepatic jaundice may give a negative response, while obstructive cases show a tendency to galactose retention. Apparently, the higher the amount of retained galactose the greater the liver damage. With a diminishing amount of galactose within the blood on repeated examinations a conclusion of improved liver function is justified. It will bear reemphasizing that the galactose test does not parallel the degree of jaundice. Very frequently in intrahepatic jaundice the galactose liver function test becomes negative before the jaundice clears. Therein lies its importance from a prognostic point of view. Whereas by the oral method in the absence of jaundice the galactose test is of no value, by the intravenous test indications of liver damage may be obtained.

The highest degrees of galactose retention are encountered in portal cirrhosis of the liver. The test is positive in 64 per cent of cases. In 36 per cent it is negative whether jaundice is present or not. We have not encountered, however, cases of cirrhosis of the liver with ascites which gave a negative intravenous galactose liver function test. Cases of cardiac ascites give persistently a negative galactose test. Therefore, this test can be used in the differential diagnosis of the etiology of ascites.

SUMMARY

The intravenous galactose liver function test, the technique of which is here described, is positive in a high per cent of cases with liver damage. It is negative in all cases where there is no liver damage. A negative test, however, does not rule out liver disease. In the early stages of jaundice it may be used in the differential diagnosis between hepatic and obstructive jaundice. In ascites it is of help in differentiating between a cirrhosis of the liver and cardiac decompensation. The progress of hepatic disease may be followed by repeated intravenous galactose liver function tests.

Gastro-Intestinal Symptoms of Pelvic Origin*

By

HARRY GAUSS, M.D.
DENVER, COLORADO

GASTRO-INTESTINAL symptoms may arise from lesions outside of the alimentary tract. They may arise from causes within the pelvis.

The "stomach" has been called the "spokesman" of the body. But the abdominal spokesman simply tells of trouble. It remains for the physician to identify the organ or diseased tissues causing the symptoms.

The pathologic background for gastro-intestinal symptomatology is quite diverse and includes lesions in the head, thorax, abdomen, and extremities. In fact there is hardly an organ in the body that does not cause digestive symptoms directly or indirectly at one time or another. This discussion is being confined to the pelvic causes of gastro-intestinal symptoms.

The literature on the pelvic origin of gastro-intestinal symptoms is rather scant.

Walschied has pointed out that in the causation of gastro-intestinal symptoms by pelvic lesions, the following factors operate: a reflex mechanism through the sympathetic and parasympathetic nervous system, the influence of hormones and mechanical compression of the lower bowel.

Moldavskaya-Svet reports a series of 169 patients who had both gastro-intestinal symptoms and gynecologic disease, in many of whom it was difficult to determine the primary syndrome. He divides the gastro-intestinal syndromes of these patients in three groups, (1) those who manifested disturbances in the motor function of the intestine as constipation or diarrhea, (2) those who manifested some inflammatory process of the large bowel or the appendix, and (3) those who manifested the peptic ulcer syndrome.

PATHOGENESIS

An analysis of the mechanism of the interrelationship of gastro-intestinal and pelvic disease shows that there are four relationships that come into consideration: (1) the anatomic, (2) the neurologic, (3) the chemical, and (4) the extraneous and accidental factors.

Mechanism of the interrelationship of gastro-intestinal and pelvic disease.

1. Anatomic Relationship,
    1. Contiguity,
    2. Ligaments,
    3. Peritoneum continuity,
    4. Peritoneal folds.
2. Neurologic Relationship,
    1. Sympathetic nerves,
    2. Parasympathetic nerves,
3. Chemical Relationship,
    1. Endocrines,
    2. Humoral factors,
4. Extraneous and Accidental Factors,
    1. Pregnancy,
    2. Tumors,
    3. Inflammations,
    4. Malignancies,
    5. Adhesions,
    6. Malpositions,
        (a) Retroversions,
        (b) Etc.
    7. Sinuses and Fistulas,
    8. Hypertrophies,
    9. Dilatations,
    10. Foreign Bodies,
    11. Fecal Impaction,
    12. Various, unusual.

1. *Anatomically* there is a close propinquity between the pelvic reproductive organs and parts of the digestive apparatus. Thus, there is a direct contiguity between the prostate or the uterus, the Fallopian tubes and the ovaries and those loops of the small intestine which descend into the pelvis as well as the pelvic colon which normally descends through the pelvic basin to lie posteriorly to the uterus or the prostate. In some individuals, the caecum and appendix occupy a low position and lie within the pelvic basin instead of being in the usual McBurney's area. This is especially true of persons of the asthenic *habitus*. In these individuals, the appendix, the right tube and the right ovary are contiguous. Inflammations of one organ readily involves the neighboring organs by the simple process of direct extension. In such individuals, salpingitis may give rise to a secondary appendicitis or *vice versa*. The clinical picture becomes very obscure as to the sequence of pathologic events. The differential diagnosis becomes difficult to make, indeed if it can be made at all. The writer has observed at the operating table on numerous occasions the appendix and right adnexa matted together into a fibrin covered mass. In these patients, all the pathology is available to direct inspection, nevertheless it is a matter of conjecture as to the order of pathologic events. Small wonder, then, that it is difficult at times to make a pre-exploratory differential diagnosis between salpingitis and appendicitis.

2. *Neurologically*, both the pelvic organs and approximately the distal half of the colon including the rectum are interrelated. Both systems derive their nerve supply from the same sources. Both are largely supplied by the parasympathetic pelvic nerves which are spinal nerves, and the sympathetic nerves derived from the inferior mesenteric plexus.

Visceral neurology according to Livingston, offers a means for satisfactorily interpreting and unifying a considerable number of seemingly isolated clinical observations.

Those organs which are innervated by spinal nerves of similar spinal levels are regarded as being of

TABLE I

Summary of case reports

Case	Age	Symptoms				Pathologic Lesion	Surgical Treatment	Results
		Duration	Gastro-intestinal	Constitutional.	Pelvic			
(1) Mrs. A. P. R.	39	5 yrs.	Flatulence, constipation alternating with diarrhea, mucus in stool, cramps, abdominal pain.	Palpitation, dizziness.	Slight dysmenorrhea.	Uterine fibroid.	Hysterectomy.	Greatly improved.
(2) Miss M. R.	32	3 mo.	Diffuse abdominal pain, R.L.Q. pain, flatulence, diarrhea alternating with constipation.	Underweight 20 lbs.	None.	Right ovarian cyst.	Right oophorectomy, prophylactic appendectomy.	Greatly improved.
(3) Mrs. G. S.	40	8 yrs.	Flatulence, constipation, abdominal distress.	Secondary anemia.	Slight, dysmenorrhea.	Fibroid uterus.	Hysterectomy.	Greatly improved.
(4) Mrs. M. C.	64	10 yrs.	Flatulence, constipation, abdominal distress.	Hot flushes, nervousness, fatigue.	Amenorrhea.	Calcified pelvic tumor.	Refused.	Unimproved.
(5) Mrs. A. L.	32	4 yrs.	Flatulence, biliousness, distress after eating, abdominal distress, epigastric fulness.	Underweight 14 lbs.	None.	Fibroid uterus.	Tumor excision.	Greatly improved.
(6) Mrs. J. S.	49	12 yrs.	Abnominal pain, cramps, nausea and vomiting, loss appetite.	Nervousness.	None.	Pelvic tumor.	Refused.	Unimproved.
(7) Mrs. L. F.	25	6 mo.	Nausea, epigastric distress, flatulence, pain in R.L.Q., peristaltic unrest, constipation.	Headache, palpitation.	None.	Chocolate cyst of right ovary.	Right oophorectomy.	Greatly improved.
(8) Mrs. S. G.	37	3 yrs.	Pain in R.L.Q., abdominal distress, diarrhea alternating with constipation, flatulence.	Urticaria, secondary anemia.	Leucorrhea, dysmenorrhea, polyuria, dysuria.	Bilateral pyosalpinx.	Bilateral salpingectomy.	Greatly improved.
(9) Miss J. B.	26	3 yrs.	Diarrhea alternating with constipation, flatulence.	Dizziness, short of breath.	Backache.	Bilateral ovarian teratoma.	Bilateral oophorectomy.	Greatly improved.
(10) Mrs. K. T.	45	10 yrs.	Indigestion, diarrhea alternating with constipation, loss of appetite, mucus stools.	Secondary anemia, underweight 20 lbs.	None.	Fibroid uterus.	Hysterectomy.	Greatly improved.
(11) Miss D. J.	50	7 yrs.	Diarrhea alternating with constipation, flatulence.	Secondary anemia, underweight 15 lbs.	Amenorrhea.	Fibroid uterus.	Hysterectomy.	Greatly improved.
(12) Mrs. J. E. H.	26	2 yrs.	Flatulence, constipation alternating with diarrhea, abdominal consciousness, mucus stools achylia.	Underweight 25 lbs.	None.	Marked retroversion.	Suspension of uterus.	Marked improvement.

embryonic, segmental relationship. Nowhere in the body is this metameric relationship better illustrated than here. The pelvic reproductive organs and the distal colon are all innervated by the pelvic nerves which originate at the second, third and sometimes the fourth sacral levels.

Sympathetic reflexes tend to follow their embryonic segmentation areas, that is, they tend to be segmental or metameric in expression. This tendency may result in the spreading of the afferent impulses to the other organs of the same spinal level, with resulting overlapping of symptoms from one system to the other.

3. *Chemically*, there is evidence pointing to the influence of the reproductive system and endocrine glands upon the gastro-intestinal tract. Thus, Artz observes that pregnancy apparently influences the gastric physiology. He reports that the free and total

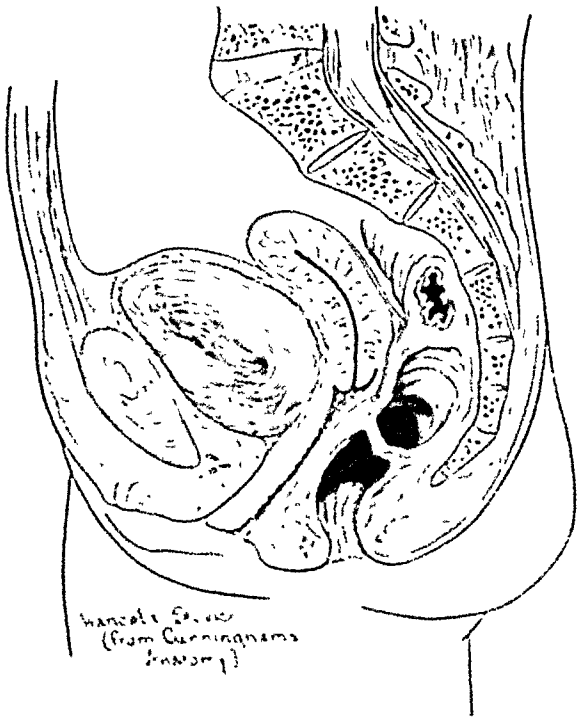

Fig. 1. Mesial section of the pelvis in an adult female showing the anatomic relationship of the reproductive system to the pelvic colon.

acidity of the stomach are lower in the pregnant than in the nonpregnant woman. Nakai likewise reported that the acidity of the stomach is lower in the pregnant woman especially during the first five months of gestation. As early as 1905, Kehrer surveyed the same relationship. In 1931, Macon of Denver, likewise made similar observations.

Strauss and Castle reported upon 21 pregnant women in whom they made 142 gastric analysis during gestation and in the puerperium. They record that 75% of the women did not secrete normal amounts of free hydrochloric acid during more than half the period of pregnancy; whereas the large majority of such patients secreted higher concentrations of hydrochloric acid after delivery; then the acid secretion of the stomach was found to be approximately three times as great as in the sixth month of gestation.

In dogs, in which the ovaries have been removed, Badylkes observed a reduction in the secretion period of the gastric juice, whereas injection of ovarian substance prolonged it. Hess and Faltitscheck believe that in menstruation the equilibrium of the vegetative nervous system is altered; this may result in hyperirritability of the parasympathetic nerves and may manifest itself in exaggerated motility and secretion of the stomach.

Klein reports an unusually interesting experiment from which he seems to have demonstrated the "humoral" influence of the reproductive system upon the digestive tract. He studied the effects of lactation on the acid secretion of transplanted gastric pouches in dogs. He made a series of such transplanted pouches into the subcutaneous tissue of the abdominal wall in dogs. These pouches had been completely separated from the old blood and nerve supply. Klein then observed that the concentration and quantity of hydrochloric acid were increased during lactation. In those animals where there had been no secretion prior to lactation, it first appeared during this period. Klein believes that the causative factor for the increased secretion at least is partly explained on a humoral basis, inasmuch as, in one dog, the transplanted pouch consisted only of mucous membrane and submucosa completely severed from the stomach and thus the vagus, the sympathetic, the gastric blood vessels, as well as the myenteric plexus were eliminated.

4. *The fourth group* is composed of the extraneous and "accidental" factors. The most important of these is pregnancy. Next to pregnancy are tumors which originate in one of the systems and which then impose their influence on the adjacent viscera by reason of the natural growth of their sphere of influence. Since tumors of the reproductive organs are of greater frequency than tumors of the lower bowel, pelvic tumors of the reproductive system occupy a special place of importance in this discussion.

Any abnormal growth in the pelvis will influence contiguous organs. At first this influence causes an irritation of the affected organ. If the irritation persists, it may develop into an inflammatory reaction.

A glance at any standard text book on anatomy giving a mesial section of the pelvis shows the close relationship of the uterus to the pelvic colon. It becomes evident that any appreciable enlargement of the uterus, irrespective of whether it is due to pregnancy, inflammation, tumor or other causes, cannot fail to press upon the colon. Pressure on the colon may result in an obstruction of its lumen and thus

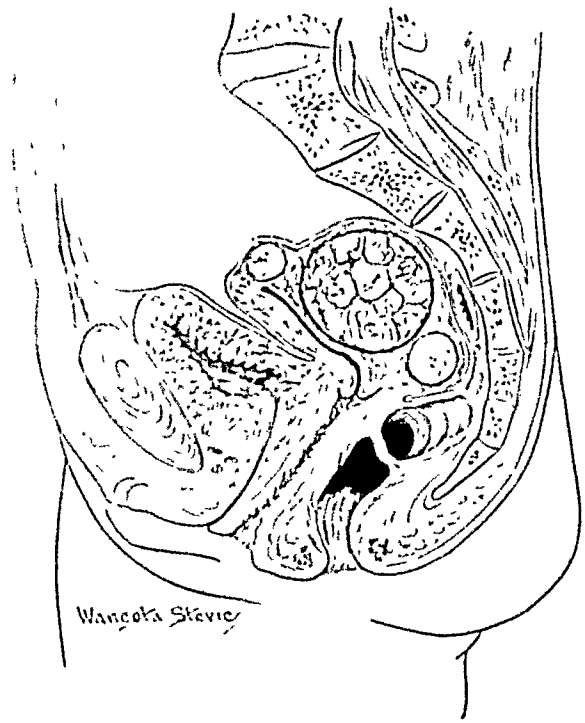

Fig. 2. Mesial section of the pelvis in an adult female showing a tumor of the uterus and its influence on the digestive apparatus resulting in compression and distortion of the pelvic colon.

Fig. 3. Roentgenogram showing a calcified pelvic tumor in patient M.C., whose presenting complaint was a digestive syndrome.

interfere with the normal movements of the intestinal content thereby causing constipation or the "colon irritation" syndrome.

In the experience of the writer, the majority of instances of gastro-intestinal symptoms due to pelvic origin, other than pregnancy, resulted from tumors.

Additional causes of gastro-intestinal irritation arising from the pelvic reproductive organs are: malpositions of the uterus, inflammations, sinuses, fistulas, adhesions, benign or malignant tumors of the ovaries, the tubes or the prostate gland.

Inflammations, hypertrophies and tumors of the prostate can disturb the gastro-intestinal tract in the same manner that corresponding disease in the female affects it Goldstein calls attention to the fact that nausea, vomiting, loss of weight, and other gastro-intestinal symptoms may indicate disease of the prostate gland.

Not all pelvic tumors necessarily disturb the digestive tract The tumor must be so located that it exerts pressure on the pelvic colon or rectum or otherwise involves them. A large cyst of the ovary may exert no deleterious effect by reason of its lack of contact with the gastro-intestinal tract. The same applies to numerous other conditions arising within the pelvis.

SYMPTOMATOLOGY

There are no pathognomonic gastro-intestinal signs or symptoms which suggest the presence of pelvic pathology. The digestive disturbances that arise are no different than those caused by a dozen different etiologic factors.

The commonest clinical syndrome is the nausea and vomiting of pregnancy. This syndrome is so general that it is usually accepted as part of the clinical manifestation of pregnancy. In fact, most text books on obstetrics list "morning sickness" as one of the presumptive signs of pregnancy. Above, we have pointed out that certain stages of pregnancy influence the gastric physiology by reducing the acid secretion.

Next in frequency to the "morning sickness" of pregnancy, is the result of pressure from pelvic tumors. This usually manifests itself in the syndrome of "irritable colon," thereby giving rise to spastic constipation, unsatisfactory stools, small caliber passages, rectal spasm, abdominal consciousness, abdominal pain, flatulence, epigastric distress. Later, the patient may develop diarrhea, mucus stools, diarrhea alternating with constipation, or mucous colitis. The cathartic and enema habit follow logically; still later, the constitutional symptoms of irritable colon develop, as chronic fatigue, insomnia, secondary anemia, introspection, etc.

We have not encountered any patients who presented the peptic ulcer syndrome as reported by Moldavshaya-Svet, although several of our patients did complain of epigastric pain, hyperacidity, and heartburn. However, we considered these to be reflex symptoms from colon irritability; such were especially noted when the X-ray showed marked spasticity of the colon but the stomach was found to be within normal limits.

The following *Case report* shows a typical instance of irritable colon caused by pelvic tumor.

Mrs. A. P. R., age 39, complained of bowel trouble of five years' duration. She stated that her stools were no longer satisfactory or normal, as they had been previously. She was constantly constipated except at times when she would experience attacks of diarrhea lasting one or two days. The stools were of small caliber, unsatisfactory and contained mucus. She had abdominal cramps and was "abdominally conscious" most of the time. She felt tired, fatigued readily, had attacks of palpitation and dizziness, and was introspective. She had no pelvic complaint but in response to questioning admitted a slight dysmenorrhea.

Physical examination: An anemic appearing woman not acutely ill; she weighed 130 pounds, was 5 feet, 7 inches in height; her pulse was 90; temperature 97.4; respiration 14; blood pressure 110/70; no lesion of heart and lungs; abdomen exhibited a spastic, palpable, and tender colon; liver and spleen not palpable; pelvic examination: a definite fibroid the size of an orange on the posterior uterine segment; it pressed on the rectum. The X-ray examination demonstrated a spastic colon throughout its entire length, associated with delayed emptying time. Blood examination revealed moderate secondary anemia. The stool contained mucus. The basal metabolic rate and urine were normal. *Diagnosis:* spastic colon, mucous colitis, fibroid of the uterus, secondary anemia.

Medical management was prescribed. This included a bland diet, intestinal lubrication, sedative therapy, and an autogenous vaccine made from the predominating stool organism. The result was unsatisfactory. A year later the patient continued unimproved, so a hysterectomy was performed. Following such, she improved and was well in a reasonable time. She remained well.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis between primary gastro-intestinal and digestive symptoms from pelvic disease is possible only by thorough, general, physical and special system examination. Only the poorly trained physician or the "inclusive" specialist fails to examine patients physically, from all angles. Particularly is his physical examination guided by the taking of a history which is, in all ways, comprehensive. Apart from history and thorough physical examination (including rectal and vaginal exploration) all possible laboratory aids, including competent X-ray studies, are requisites if one is to avoid pitfalls, diagnostically

and therapeutically. Patient No. 4 here reported, at X-ray examination, was found to have a calcified, pelvic mass; advantage, likewise, should be taken of injecting the uterus and the tubes by substances opaque to the X-ray, when digital examination suggests pathology.

A careful inquiry into the pelvic history of each patient frequently will disclose anomalies of the menstrual cycle, dysmenorrhea, metrorrhagia, amenorrhea, dysuria, polyuria, painful coitus, etc.; the pelvic examination usually will demonstrate pathology or visceral malpositions. The writer frankly confesses that it is not an uncommon experience in his practice to have the pelvic examination reveal a pelvic mass in patients in whom it was not suspected previously and where the history predominantly was that of dyspepsia or alimentary tract irritability. In the diagnosis of digestive complaints, one must be *suspicious* of disability in systems apart from the gastro-intestinal tract, before condemning it to harboring primary pathology. Eternal vigilence is the price of diagnostic accuracy.

TREATMENT

The first principle is to remove the cause. Fortunately, in many patients, this can be done satisfactorily by combined medical and surgical procedures. Benign tumors can be removed, malignant tumors treated according to indications, malposition of viscera, such as retroversion, can be corrected, inflammations appropriately managed as findings warrant. In those dyspeptic patients where the essential anomalies lies in pelvic lesions, the removal or alleviation of such disturbances, commonly is followed by digestive tranquility.

Primary gastro-intestinal disease may coexist in a patient who has pelvic disease particularly in patients of middle age. Thus, a patient with acute salpingitis also can harbor a peptic ulcer, gall stones or true colitis. Hence, even should pelvic examinations disclose pathology which may be assumed to account for dyspeptic upsets, one never should be willing to allow his final diagnosis to so rest until by all available, modern means, he has excluded actual disease in the alimentary tract and its associated organs.

CASE REPORTS

We are reporting in tabular form for purpose of brevity, a series of twelve patients other than those of pregnancy, with typical gastro-intestinal syndromes which were caused by pelvic pathology. These disturbances occurred in women whose *ages* ranged from 26 to 61. The *symptoms* were experienced for from 6 months to 12 years. The *gastro-intestinal symptoms* generally encountered in the irritable colon group were: constipation, unsatisfactory stools, small caliber stools, mucus stools, flatulence, rectal spasm, peristaltic unrest, constipation alternating with diarrhea, "abdominal consciousness," epigastric distress, heartburn.

The *constitutional symptoms* encountered were: palpitation, dizziness, underweight, secondary anemia, "hot flashes," fatigability, nervousness, headache, urticaria, dyspnoea. The *pelvic symptoms* experienced were leukorrhea, dysmenorrhea, backache, amenorrhea, dysuria, polyuria.

The pelvic lesions found were: fibroid tumor of the uterus in five, unilateral ovarian in two, bilateral teratoma of the ovaries in one instance, bilateral pyosalpinx in one, an undetermined calcified pelvic tumor in one patient, a pelvic tumor of undetermined nature in one patient and a marked uterine retroversion in one patient.

In all of these patients, symptomatic treatment for the gastro-intestinal syndrome was tried, but the results were unsatisfactory. Surgical treatment of the pelvic lesion was advised in all cases. Ten patients submitted to surgery and greatly improved. Two patients refused surgery and remained unimproved. In the group that was operated upon, relief of the gastro-intestinal symptoms seemed to be due to the eradication of the pelvic pathology or to corrections of anomalies. This series is small but we believe that its citation will emphasize sufficiently the necessity for considering seriously the possibilities of pelvic pathology, particularly in women, who are exhibiting dyspepsia—often not "true to type" for definite organic disease of the digestive system

SUMMARY

1. Gastro-intestinal symptoms may arise from lesions outside of the gastro-intestinal tract.

2. They may arise from causes within the pelvis.

3. An analysis of the mechanism of the interrelationship of gastro-intestinal and pelvic disease shows that there are four possible relationships that come into consideration, namely the anatomic, the neurologic, the chemical, and the extraneous and accidental factors.

4. Pregnancy constitutes the etiologic factor of greatest importance within the pelvis which causes digestive symptoms. Next in importance are pelvic tumors which impose their influence on the adjacent bowel.

5. There are no gastro-intestinal symptoms pathognomonic of pelvic origin.

6. The common gastro-intestinal syndromes of pelvic origin are, first, the morning sickness of pregnancy, and second, the colon irritation syndrome caused by pelvic tumors, but any digestive symptom may be encountered.

7. The diagnosis of pelvic lesions causing gastro-intestinal symptoms is usually arrived at from a consideration of the pelvic history and thorough general as well as pelvic examination.

8. A pelvic as well as a rectal examination constitute an integral part of every well conducted gastro-intestinal examination.

9. A series of twelve patients illustrating typical examples of gastro-intestinal complaints due to pelvic disease is reported.

10. Symptomatic medical treatment for the gastro-intestinal complaints was unsuccessful in these patients.

11. In ten of the patients, the successful surgical treatment of the pelvic lesion was followed by a disappearance of the gastro-intestinal complaint.

12. In two patients, surgical treatment of the pelvic lesion was refused, and these patients remained unimproved.

SECTION II—*Experimental Physiology*

The Composition of Human Gastric Juice Secreted in Response to Histamine Administration*

By

C. GWENDOLINE TOBY, B.A.
MONTREAL, CANADA

THE investigation of the gastric mucosa of mammalian animals presents great difficulties, owing partly to the very complex structure of the gastric mucous membrane—which includes several types of gland—and partly to the necessity of dealing with the secretions of all the gastric glands and epithelia, not separately, but as a mixture, which is referred to as "the gastric juice."

A great advance in the study of the secretory function of the gastric mucosa has been made in recent years. In this research histamine has proved a most useful agent. In the dog and cat, histamine presumably stimulates secretion in the parietal cells only. *The vagus nerve, on the other hand, influences the activity of the peptic as well as of the parietal cells.* Since no detailed study had ever been made of the two extremely different types of gastric juice obtained respectively by the administration of histamine and by sham-feeding, the writer has attempted an investigation of this problem. First of all, the effect of different types of stimuli on the composition of the gastric juice was studied in the dog, the results being reported elsewhere (Toby, 1936). In the present paper data obtained from a study of human gastric juice will be considered. Samples of gastric juice from normal human individuals and from several patients in the Royal Victoria Hospital, Montreal, were analysed. The same methods of analysis were used in these cases as in the animal experiments just referred to, so that a comparison could be made of the course and composition of the hydrolysed gastric secretion produced by histamine in such different species as man and the dog.

The literature concerning the study of gastric function presents a great mass of conflicting results. Some of the discrepancies would appear to be due to differences in experimental conditions or to faulty technique. Conclusions frequently have been based on clinical data alone, where the chances of error are greater than in the case of experimental animals. It is evident from experimental work on the dog that the general condition of the organism plays a great part in the response elicited by any given type of stimulus. Variations in the level of the blood chlorides, vitamin deficiencies, or changes in the proportion of the main constituents of the diet all influence the secretory activity of the stomach. Although the responses in the dog and the human respectively may not be identical even under approximately the same conditions, it *seemed desirable to compare data obtained on man with those already obtained on the dog, where a* greater number of factors could be standardized and where there was less likelihood of error or contamination in the collection of samples of gastric juice.

In brief, the results obtained by the writer (*l.c.*), using dogs with oesophagotomy and a gastric fistula, and a dog with a Heidenhain pouch, are as follows. The composition of the gastric juice varies according to the stimulus employed, which may act selectively on different groups of cells in the gastric mucosa. Two extremely different types of gastric juice are obtained after subcutaneous injection of histamine and after sham-feeding or pilocarpine injection. In the former case the juice is poor in organic material and enzymes, in the latter very rich in these constituents. There is, however, little difference in the total chloride concentration and total acidity of the gastric secretions produced by sham-feeding and histamine respectively. When pilocarpine is used as a stimulus, the total acidity of the secretion is markedly lower and the concentration of total chloride a little lower than when sham-feeding or histamine is employed. At times practically all the chloride present is in the form

*From the Department of Physiology, McGill University.
Submitted October 16, 1936.

TABLE I

Total volume and average concentration of various constituents of the gastric juice for the whole secretory period after repeated subcutaneous injection of histamine or repeated 5-minute sham-feeding with meat in two dogs ("S" and "B") with œsophagotomy and gastric fistula.

Animal and Stimulus	Duration of secretion min.	Vol. c.c.	Mucus c.c.	Free HCl mg. %	Total acid (as HCl) mg. %	Total Cl mg. %	Neutral Cl (determined) mg. %	Neutral Cl (calculated) mg. %	Mucin (as glucose) mg. %	Total N mg. %	Pepsin Mett's units
Dog "S": Histamine	97	237	0.9	487	553	570	32	32	1.6	14.5	6
Dog "S": Sham-feeding	110	166	7.6	408	536	571	52	48	20.7	44.8	180
Dog "B": Histamine	125	132	0.2	361	510	567	—	41	—	19.0	16
Dog "B": Sham-feeding	111	143	3.5	418	555	570	—	35	—	47.0	219

of HCl. These slight variations in the total chloride are probably due either to contamination of the secretion *from the parietal cells with varying amounts of* fluid less rich in chlorides, secreted by other groups of cells, or, to a less extent, to changes in the concentration of chlorides in the blood plasma. Under the influence of any one stimulus, the gastric glands produce a secretion in which the acidity runs more or less closely parallel to the total chloride concentration; but as soon as a new stimulus is superimposed on the first, or towards the end of the secretory period, there is an alteration in the activity of different cellular groups and the acid and chloride are no longer secreted in parallel concentration. Since the volume and the total chloride content of the secretion vary little under different stimuli, whereas the organic content may be ten to twenty times greater than the minimum, it was concluded that the major part of the chlorides and the fluid of the gastric juice is produced by the parietal cells.

In order to facilitate the comparison of the data obtained on the dog with those relating to the composition of human gastric juice, an abbreviated table is given here of average results reported in the above-mentioned work (Table I).

METHODS

The persons to whom histamine injections were given, for the purpose of obtaining samples of gastric juice, were grouped as follows:

(1) Subjects with normal gastric function:
  (a) young men (students),
  (b) selected from among hospital patients;
(2) Patients with the under-noted gastro-intestinal diseases:
  (a) gastritis, functional diseases of the stomach, etc.,
  (b) gastric ulcer,
  (c) duodenal ulcer.

The last meal before the test was always taken on the previous evening. In the morning, the fasting juice was removed from the stomach. 0.5 to 1.0 mg. of histamine (ergamine acid phosphate) was then injected subcutaneously and gastric juice aspirated at 10- or in some cases 15-minute intervals, over a period of 60 to 80 minutes. Contamination with saliva was avoided as far as possible. Samples which, owing to duodenal regurgitation, were either dircolored with bile or abnormally large in volume, were discarded. As gastric juice may have passed into the duodenum between aspirations, the figures for the total amounts secreted must be considered as approximate. The volumes for the ten-minute intervals may also be somewhat inaccurate, as in some instances the aspiration was not complete. Smoothness and regularity of the volume curves would tend to make the aspirations appear complete.

The analytical methods employed were the same as those which served in the investigation of canine gastric juice (Toby, *l.c.*), this providing a good opportunity for comparing the composition of the gastric secretion in man and in the dog.

The total and free acidities of the juice were determined by titration with 0.01 N NaOH, phenolphthalein and Töpfer's reagent being employed as indicators. The salmon pink end-point for free HCl, suggested by Michaelis, was used. The total chloride was determined by Wilson and Ball's (1928) modification of Van Slyke's method and expressed as Cl, and the neutral chloride was estimated by ashing the juice and then determining the chlorides by the same method. The neutral chloride values were checked by calculating the difference between the total chloride and the Cl of the HCl. The variations were within the limits of experimental error.

The mucin was estimated by determining the reducing power of the juice by the Hagedorn and Jensen method (Peters and Van Slyke, 1932) after acid hydrolysis, the result being expressed as glucose. Reducing substances were also determined in the unhydrolysed juice, and this value was subtracted from that obtained after hydrolysis, so that the final figure represented glucose split from the mucoprotein.

The pepsin was determined by Nirenstein and Schiff's modification of Mett's method (Hawk and Bergeim, 1927).

The total nitrogen was estimated by digesting the juice by Kjeldahl's method, distilling the NH_3 in a modified Parnas-Wagner micro-Kjeldahl apparatus, and titrating with 0.01 N NaOH (Hawk and Bergeim, 1927).

RESULTS

Normal subjects. The composition of the gastric juice obtained after histamine injection was investigated in three young, normal subjects (Cases 1, 2 and 3). Of these control cases, No. 3 was rejected, since the samples showed a definite anacidity. In this apparently healthy young man the average total acidity of the gastric juice was rather low (125 mg. per cent), the total chloride content amounted to only 372 mg. per cent, and the neutral chloride to 243 mg. per cent (thus forming 64 per cent of the total chloride). The peptic power, however, was high, averaging 1115 Mett's units.

A complete analysis of the gastric juice in Case 1 is given in Table II by way of example. The average

figures for the whole secretory period in Cases 1 and 2 are shown in Table III. The gastric juice of four hospital patients, who were considered to have normally functioning stomachs, was also investigated. The latter have been included in the normal group, but with certain reservations on account of the unnaturally wide variations in volume, the low level of total chloride and total acid, and the abnormally high neutral chloride content of the juice.

The following conclusions may be drawn from a comparison of Cases 1 and 2 with the data obtained from the experiments on dogs (see Table I). The total acidity of the "histamine" gastric juice in humans (377 and 447 mg. per cent) is somewhat lower than in dogs with oesophagotomy and gastric fistula (553 and 510 mg. per cent) but somewhat higher than the "histamine" juice obtained from a dog with a Heidenhain pouch (436 mg. per cent). In two of the samples of juice from Case 2, the free acidity amounted to 424 and 438 mg. per cent respectively, thus approaching or equalling the values obtained in dogs. The average total chloride values (510 and 553 mg. per cent) approximated to those found in the "histamine" juice of two dogs (570 and 567 mg. per cent). Since in humans it is difficult to prevent entirely the contamination of the gastric juice with saliva, although this can be done in dogs with oesophagotomy, the small divergences in the acid concentration of human and canine gastric juice are to be ascribed to this rather than to differences in the secretory properties of the gastric mucous membrane in the two species. That it is highly important to exclude the possibility of contamination of the gastric juice by mouth secretions has been shown by Carlson (1919) in experiments on human subjects. Carlson found that the gastric juice obtained through a fistula had higher free and total acidity in cases of oesophageal obstruction (0.40 and 0.48 per cent) than in cases where the oesophagus was patent (0.34 and 0.44 per cent). It would seem safe to conclude therefore that there is little difference in the acid-producing properties of the gastric mucosa in dog and man.

Further observation, however, shows that normal human gastric juice and canine gastric juice are not alike in all respects. In the first place, we saw that the values for neutral chloride are much higher in normal human "histamine" juice (132 and 103 mg. per cent) than in the juice of dogs with oesophagotomy and a gastric fistula (32 and 41 mg. per cent). Only in the dog with a Heidenhain pouch was the concentration of neutral chloride (137 mg. per cent) observed to approach that of human gastric juice. It is possible that continuous irritation of the mucosa of the pouch by the drainage tube may have been partly responsible for this augmentation of the neutral chloride.

The difference in the concentration of neutral chloride in the normal human and in canine gastric juice may perhaps be explained by the fact that in the fundic part of the stomach the proportion of mucoid cells ("chief cells of the neck") to peptic cells is much greater in the human than in the dog (cf. description, drawings and photomicrographs in Zimmermann, 1925; Plenk, 1932; Bowie and Vineberg, 1935).

Next, the organic constituents must be compared. The values for total nitrogen, dissolved mucin and pepsin are undoubtedly much higher in human gastric juice elicited by histamine than in canine gastric juice produced by the same stimulus. In the dog, the amounts of mucin and pepsin secreted are practically negligible, and the nitrogen concentration is only about one-fourth that of the gastric secretion in the human. Again, samples of secretion from a Heidenhain-pouch dog had a much higher nitrogen content, although still only about half that of human gastric juice.

Especially striking is the extremely high concentration of pepsin in samples from some of the human

Case 8: chronic gastritis; peritoneal adhesions (?); suspected gastric ulcer.
Case 10: gastric ulcer on lesser curvature.
Case 12: gastric ulcer.
Case 13: gastric ulcer (?).
Case 14: pyloric ulcer with obstruction.
Case 15: ulcer on lesser curvature.
Case 16: gastric ulcer (?); hematemesis; flattened duodenal cap.
Case 17: duodenal ulcer, penetrating and walled off
Case 18: duodenal ulcer polycythemia.
Case 19: duodenal ulcer.

subjects. Pepsin sometimes reached single values as high as 2304 and 2025 Mett's units, while averages might be as high as 1603 and 1115. Such values cannot always be obtained even by electrical stimulation of the vagus in acute experiments on dogs.

Several tentative explanations of this fact are here advanced. It might be suggested that: (1) In man histamine acts upon the peptic as well as upon the parietal cells, although in the dog and cat it only affects the latter. In that case histamine would be one of the strongest stimulants of the peptic cells in man. That this explanation is untenable, however, will be shown in the paper immediately following (Toby (2)). Human peptic cells produce a stronger protease than do the peptic cells of the dog and cat. (3) There is perhaps in the gastric mucosa of man a relatively greater number of peptic cells than in the gastric mucosa of the dog and cat. It has been shown by Aschoff (1923) and by Dr. D. J. Bowie (in a paper presented to the American Anatomical Society in April, 1936—personal communication) that in the dog and cat the peptic cells occupy the basal part of the gastric tubules. The rest of the tubule is lined with mucoid cells ("chief cells of the neck") and parietal cells. The peptic cells are most numerous in the glands of the fundic part of the stomach and less abundant in those nearer to the pyloric part. In the "intermediary zone" *("Zwischenzone")* of Aschoff the tubules contain only mucoid and parietal cells. In man the arrangement of the cells may be different; it is possible that there may be a larger proportion of peptic cells in some regions of the human gastric mucosa than in the corresponding regions of the canine gastric mucosa, or that the cells may be distributed more evenly throughout the entire fundic portion of the stomach in the human.

The relative difference in the amount of histamine administered to dogs and to human subjects must also be taken into consideration. The dogs received far larger doses in proportion to their body weight. Dogs of about 15 kg. received 0.75 to 1.0 mg. of histamine. Human subjects weighing 60 to 70 kg. received only 0.5 to 1.0 mg., or proportionately about one-fifth the amount administered to dogs. Since in the dog histamine acts almost exclusively on the parietal cells, the concentration of pepsin in the gastric juice secreted in response to applications of this substance will diminish as the volume of fluid increases. This is the so-called "washing-out" effect described by Babkin (1930).

In Cases 1 and 2, the free acidity of the juice remained high almost to the end of the secretory period. The total chloride content and total acidity were somewhat lower in the last samples, when the flow of gastric juice had greatly diminished. This is not in agreement with the finding of MacLean *et al* (1928a, b, c) that towards the end of the secretory period a neutral fluid is produced which replaces the acid secretion of the gastric glands. On the contrary, it would appear more likely from the results obtained by the writer (Toby, *l.c.*) and from the work of others (Webster, 1929; Bolton and Goodhart, 1931, 1933, and Hollander, 1934) that the neutralization of small amounts of acid juice present in the stomach is effected by the alkaline mucus secretion.

Thus, the gastric juice secreted by the normal human stomach, in response to a comparatively small dose of histamine, differs little in its acid properties from canine gastric juice, although it is richer than the latter in all the organic constituents and in neutral chloride.

Pathological Cases. Table III shows the volume of gastric secretion and the average concentration, for the whole secretory period, of its various components, determined in a representative number of patients suffering from various forms of gastro-intestinal disease, as well as in two normal cases (Nos. 1 and 2). In all the cases of gastric dysfunction without exception the total acidity was lower than in the normal cases, and only on a few occasions did it even reach half the concentration noted in the latter. In several cases the free acidity was zero, or very low. The total chloride concentration in a few of the cases studied was close to normal (*e.g.*, 492 and 481 mg. per cent), while in most of the others it was decidedly below normal. The neutral chloride concentration in all the cases of gastric dysfunction was above normal, with one exception (Case 7). In addition, the proportion of neutral chloride to total chloride was in all cases much higher than usual.

In Case 7 (diverticulum and functional disorder of the stomach) the neutral chloride content was low (101 mg. per cent), as was also the total chloride content, so that the proportion of chloride as neutral chloride was relatively very high (67 per cent). The peptic power of the juice was low. Undoubtedly in this case the activity of both the parietal and the peptic cells was depressed. It seems probable that the mucosa secreted a small amount of acid fluid which was partly neutralized and partly diluted by another secretion having a lower concentration of neutral chloride. The juice contained a fairly large amount of dissolved mucin (26.9 mg. per cent), which might have come from either the peptic or the mucoid cells. Again, there is the possibility that the parietal cells might have lost their ability to concentrate chloride, so that, although the volume of fluid passing through them might be as great as ever, the chloride concentration of the juice would be below normal.

The three cases of duodenal ulcer (Nos. 17, 18 and 19) gave results somewhat different from those of the cases in which the stomach was affected. In response to 1.0 mg. or even 0.5 mg. of histamine the gastric glands produced a juice in which the free and total acidities and the total chloride content were very high. The proportion of neutral chloride to total chloride approximated to that observed in the normal cases (Nos. 1 and 2).

DISCUSSION

From experimental data obtained on canine gastric mucosa it appears evident that the main functions of the parietal cells are to concentrate chloride to a level above that of the chloride in the blood and to convert it into hydrochloric acid. This is borne out by the analyses of the gastric juice of normal human subjects described in the present paper. The only difference between the composition of human gastric juice and that of canine gastric juice in respect to chloride content is that the former is somewhat richer in neutral chloride than the latter. All the gastric pathological cases examined by the writer showed impairment of one or both of these functions. This is well illustrated (see Table III) in one case of chronic gastritis (No. 8) and six cases of gastric ulcer (Nos. 10, 12, 13, 14, 15 and 16). In all these cases the total acidity is very much below normal, and in all but one (No. 10) the total chloride content is well below normal, while the neutral chloride in all cases is above normal. The volume of secretion is in several cases (Nos. 8, 15 and 16) approximately as great as in normal subjects. In the other cases it is markedly reduced (Cases 10, 12, 13 and 14).

If it be admitted that in the human gastric mucosa the greater part of the chloride and the fluid of the secretion are produced by the parietal cells, as is the case in the canine gastric mucosa, then it is conceivable that in the above instances the parietal cells lost first, their ability to convert neutral chloride into hydrochloric acid, and later, their ability to concentrate chloride. This explanation would be in agreement with Rosemann's theory, recently upheld by Katsch, Baltzer and Brink (1934), that the variations in the acidity of the gastric juice are due to the varying concentration of the HCl secreted by the parietal cells. Although the levels of total acid, total chloride and neutral chloride vary widely from case to case, the percentage of the total chloride present as neutral chloride is more or less constant and well above normal (see Table III). Two normal cases show respectively 19 and 26 per cent of neutral chloride; five gastric ulcer cases, 48 to 59 per cent; and one gastric ulcer case as much as 72 per cent. One case of diverticulum of the greater curvature, with functional disease of the stomach, and one of chronic gastritis show 67 and 83 per cent respectively. In contrast to these, and falling more or less within the normal range, are three duodenal ulcer cases in which the concentrations of neutral chloride are respectively 17, 28 and 31 per cent of the total chloride concentration.

Another tentative explanation of the deviations from normal observed in the composition of the gastric juice in pathological cases might be put forward, namely, that under the influence of a pathological process the secretory activity of different cellular groups included in the gastric glands only changes quantitatively as a rule. This explanation would accord with the theory, originating from this laboratory, concerning the regulation of the secretory activity of compound glands, such as the gastric glands (Babkin, 1931, 1934). Thus it might be that the amount of normal acid secretion produced by the parietal cells was greatly diminished in the cases in question, whereas the activity of those cells—mucous cells, "chief cells of the neck," peptic cells—which discharge a slightly alkaline secretion, containing a comparatively low concentration of neutral chloride, was markedly increased. Since the visible mucus in the gastric juice varied greatly from patient to patient, and the concentration of pepsin in the gastric secretion of the various cases could not be related to the concentration of neutral chloride, it is reasonable to assume that the chief source of the fluid containing the neutral chloride was neither the surface epithelium cells nor the peptic cells. Thus the mucoid cells ("chief cells of the neck") seem to be the most probable source of the neutral chlorides and base. Unfortunately we have no direct proof of this assumption, although it seems to be a reasonable one. There is as yet no proper method for ascertaining the degree of activity of the mucoid cells. The mucin which is dissolved

in the gastric juice probably arises both from the mucoid and the peptic cells. Therefore in pathological cases the concentration of mucin in the juice cannot be used as an indication of the functioning of the mucoid cells. In normal animals the values for pepsin, mucin and organic material practically parallel each other throughout the duration of the secretion. In the human cases of gastric dysfunction here studied the parallelism between these constituents occurred irregularly or was absent altogether, according no doubt to the extent to which the functions of different groups of cells were impaired.

Teorell's (1933, 1935) "diffusion theory" does not satisfactorily explain the altered properties of the gastric juice in cases of gastric dysfunction (see Table III). According to this theory the neutralization of HCl in the stomach is effected not by an alkaline secretion but by means of an interchange between the H ions of the juice and the Na ions of the tissue fluid. In the majority of our cases, not only was the total acidity of the juice diminished, but also the total chloride concentration. In terms of Teorell's theory, this phenomenon would be due to the fact that not only the H ions but Cl ions likewise are diffused back extremely rapidly into the tissue. It is very doubtful that this could occur in the freshly secreted gastric juice during the short interval of 10 to 15 minutes between two aspirations.

There is no evidence that in any of the pathological cases studied the acid gastric juice was neutralized at the height of its secretion by the alkaline pyloric juice. If this were so, an exceedingly great hypersecretion of pyloric juice would have to occur.

The limited number of pathological cases examined during this investigation does not justify the adoption of either of the explanations suggested above. However, the detailed study of the gastric secretion in these cases has yielded important information concerning the abnormal functioning of different groups of secretory cells which participate in the formation of the gastric juice. By following up this line of investigation it may be possible in the future to localize the exact seat of the pathological process in the gastric mucosa.

SUMMARY

1. Normal human gastric juice secreted in response to histamine administration is in many respects similar both qualitatively and quantitatively to canine gastric juice obtained by means of the same stimulus.

2. The concentrations of acid and total chloride in human gastric juice approximate very closely to those found in canine gastric juice. They remain more or less constant during the greater part of the secretory period but diminish as the secretion becomes less.

3. There is a higher concentration of neutral chloride in normal human gastric juice than in canine gastric juice. A considerable amount of organic material (*e.g.*, mucin, pepsin) as well as of nitrogen is always present in the former.

4. In all the pathological cases studied, in which an impairment of the gastric secretory function might be presumed, the gastric juice showed a smaller concentration of total chloride, and a greater concentration of neutral chloride, than under normal conditions. In most cases the volume of the secretion was reduced, and also the concentrations of free and total acid.

5. In the cases of duodenal ulcer investigated there was a tendency to hypersecretion of the gastric juice; the total chloride content of the juice was high; the percentage of total chloride present in the juice as neutral chloride was approximately normal, and the acidity was fairly high.

I have great pleasure in expressing my thanks to Dr. B. P. Babkin, as supervisor of this work, for his kindly interest and most helpful criticisms and advice. I am indebted also to the Department of Experimental Surgery and Medicine of McGill University for facilities and assistance, and to Drs. John Armour and A. M. Vineberg of the Royal Victoria Hospital, Montreal, for making this investigation possible. I am obliged to Miss J. F. Oswald for assistance in the preparation of the manuscript.

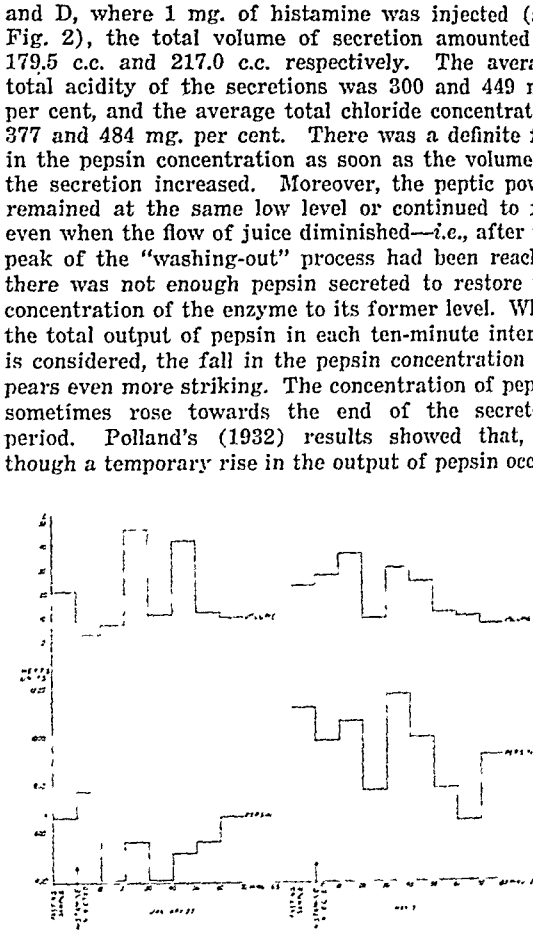
Does Histamine Stimulate the Secretory Activity of the Peptic Cells in Man?*

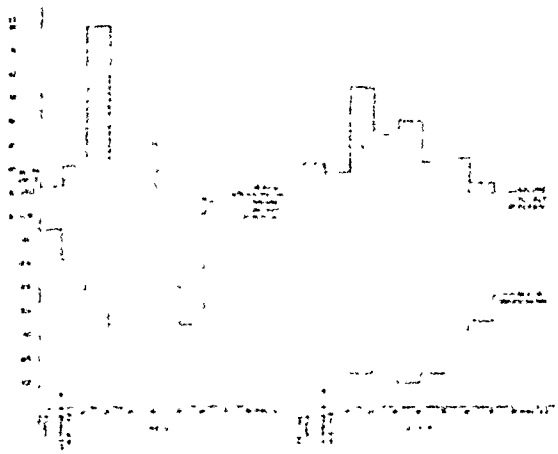


By
C. GWENDOLINE TOBY, B.A.
MONTREAL, CANADA

IT has been shown by previous investigators who have studied the effect of histamine on the gastric glands in the dog and cat (Babkin, 1930; Vineberg and Babkin, 1931; Gilman and Cowgill, 1931; Baxter, 1934; Bowie and Vineberg, 1935) that this substance stimulates secretory activity in the parietal cells exclusively. Moreover, it seems probable that under certain circumstances histamine inhibits the secretory activity of the peptic cells (Alley, 1935).

During an investigation recently carried out by the writer (Toby, 1936) numerous examples of the selective action of histamine on the parietal cells of the canine gastric glands were obtained. It was found that in the dog histamine in the doses employed did not stimulate the discharge of pepsin. However, a great many clinicians hold that the administration of histamine in man results in an increased output of pepsin (Polland, 1932; Bloomfield and Polland, 1933; Blakely and Wilkinson, 1933; Rivers, *et al*, 1936; Osterberg, *et al*, 1936). They disagree with the view, held by many of the experimental physiologists working on animals, that only the parietal cells are actively engaged in secretion after histamine administration and that pepsin is merely "washed out" from the glandular tubules into which it is slowly and continuously discharged from the peptic cells.

This apparent difference in the effect of histamine stimulation of the gastric glands in the dog or cat as compared with man might be attributable to one of the following causes: (1) the mechanism regulating the secretory activity of the gastric glands in man may be fundamentally different from that in carnivorous animals, or (2) the experimental conditions and the methods of stimulation employed may have been such as to give different results. It was decided to test out the latter of these two assumptions as being the easier of attack. As has been mentioned in the preceding paper (Toby), the doses of histamine administered to animals were much larger than those usually administered to man (i.e., 0.50 to 0.66 mg. per 10 kg. body weight in the dog as compared with 0.10 mg. or less per 10 kg. body weight in man). Mrs. M. M., who was a patient in the Royal Victoria Hospital, Montreal, for several months, suffering from ulcer on the lesser curvature of the stomach near the esophagus, provided an opportunity for studying repeatedly the effect of both small (0.5 mg.) and large (1.0 mg.) doses of histamine on the gastric secretion.



From a great number of analogous experiments carried out on this patient, four have been selected (A, B, C and D). In A and B the secretory effect of 0.5 mg. of histamine may be seen, and in C and D the effect of 1.0 mg. of histamine. The course of the gastric secretion and the concentration of pepsin in each case are represented graphically in Figs. 1 and 2. The usual small dose of histamine (0.5 mg.) was given in Tests A and B (see Fig. 1) and provoked the secretion of respectively 139 c.c. and 161 c.c. of gastric juice, in which the average total acidity (382 and 333 mg. per cent) and the average concentration of total chloride (505 and 457 mg. per cent) were moderately high. The peptic power of the juice was moderate in A, and rather higher in B. There was a tendency in both instances for the pepsin to diminish with the increase in the volume of the secretion. In Tests C and D, where 1 mg. of histamine was injected (see Fig. 2), the total volume of secretion amounted to 179.5 c.c. and 217.0 c.c. respectively. The average total acidity of the secretions was 300 and 449 mg. per cent, and the average total chloride concentration 377 and 484 mg. per cent. There was a definite fall in the pepsin concentration as soon as the volume of the secretion increased. Moreover, the peptic power remained at the same low level or continued to fall even when the flow of juice diminished—*i.e.*, after the peak of the "washing-out" process had been reached there was not enough pepsin secreted to restore the concentration of the enzyme to its former level. When the total output of pepsin in each ten-minute interval is considered, the fall in the pepsin concentration appears even more striking. The concentration of pepsin sometimes rose towards the end of the secretory period. Polland's (1932) results showed that, although a temporary rise in the output of pepsin occur-

C D

Fig. 2. Relation of concentration and total output of pepsin to fluid volume in gastric secretion produced by 1 mg. histamine. (Case "M. M.": Tests C and D).

red after each injection of histamine, there was a definite fall in the pepsin concentration during the course of the experiment, as may be seen in all his four charts.

The only interpretation that might be put upon these data would seem to be that *histamine is a selective stimulus* which acts exclusively on the parietal cells, or at least much more strongly on them than on those concerned with the elaboration of pepsin. Further confirmation of this is afforded by the fact that the greater the volume of the secretion, the higher is the acidity and the lower the organic and enzymatic content of the juice.

It must be borne in mind that in all the cases investigated by the writer (see also preceding paper) there was a "spontaneous" secretion of gastric juice before the histamine was injected. The histamine secretion was superimposed on this spontaneous secretion, and was diluted by it. The peptic power of the spontaneous juice differed very much in the various cases and in some of the specimens it was fairly high. Hence in experiments on man the pepsin output cannot be taken as an indication of the effect of histamine on the peptic cells, although it has been considered as such by several clinical investigators (*e.g.*, Polland, 1932; Bloomfield and Polland, 1933). Experiments on man do not present so clear a picture in this respect as do animal experiments, since in the latter there may be no secretion for a very long time before histamine is administered and the true effect of histamine on the resting gastric glands may be observed.

The following figures show how important it is to determine the peptic power of the "fasting" juice in order to arrive at a proper evaluation of the histamine test in man. In the so-called "fasting" gastric juice of the subjects studied, all of whom were pathological cases except Case 1 (cf. Table III of the preceding paper), the peptic power was roughly of the same magnitude as the average peptic power of the "histamine" gastric juice of the same individual.

Peptic Power of Gastric Juice (in Mett's units)

Case No.	"Fasting" Juice	"Histamine" Juice
1	1936	1603
4	502	499
5	1024	1111
6	433	511
8	644	526
10c	256	479
12	1414	1045
15	400	690
16	1296	937
17	traces	178
18	701	788

If histamine stimulates the peptic cells, then in the gastric juice secreted after histamine administration, the values for pepsin should be more uniform, like those for the total chloride and hydrochloric acid, and the concentration of pepsin should always rise above the fasting level.

CONCLUSION

In the light of the data at our disposal, it seems reasonable to conclude that histamine does not augment the output of pepsin, and that "histamine" gastric secretion reflects the state of activity of the peptic cells before the injection of this substance. There seems to be no need therefore to suggest a new theory to explain the action of histamine on the human gastric glands. The conception formulated by previous investigators with respect to the gastric glands of carnivorous animals, namely, that histamine stimulates the parietal cells exclusively, may be safely applied to human gastric glands as well.

I have great pleasure in expressing my thanks to Dr. B. P. Babkin for his kind interest in this work and his most helpful criticisms and advice. I am indebted also to the Department of Experimental Surgery and Medicine of McGill University for facilities and assistance, and to Drs. John Armour and A. M. Vineberg of the Royal Victoria Hospital, Montreal, for making this investigation possible. I am obliged to Miss J. F. Oswald for assistance in the preparation of the manuscript.

Gastro-Intestinal Studies

VI. The Volume of the Gastric Juice in Pernicious Anemia*

By

PAUL J. FOUTS, M.D., O. M. HELMER, Ph.D.

and

L. G. ZERFAS, M.D.

INDIANAPOLIS, INDIANA

IN a previous article (1) an attempt was made to correlate the findings in the gastric juice of 47 patients having pernicious anemia with the clinical condition of the patient, the degree of central nervous system involvement, and the maintenance dosage of liver extract. Little or no correlation could be found at that time. It was stated, however, that the patients who had lower red blood cell counts tended to have smaller volumes than those having higher counts. Also, the patients with early or no central nervous system involvement more often had greater volumes of gastric juice than did those with moderate to advanced central nervous system involvement.

Isaacs and Goldhamer (2) concluded that in pernicious anemia the deficiency in intrinsic factor is a quantitative rather than a qualitative deficiency. Goldhamer (3) stated that in patients with untreated pernicious anemia there is a direct relationship between the amount of gastric juice secreted per hour by the patient and the red blood cell level—that is, the greater the gastric secretion the higher the red blood cell level. He concluded that erythropoiesis depends in part at least upon the action of the intrinsic factor and that the rate of red blood cell formation is related to the amount of intrinsic factor produced.

METHOD OF STUDY

It is the purpose of this paper to present the findings in the gastric juice of 125 patients having pernicious anemia. A total of 160 examinations was made.

After removal of the fasting gastric contents each patient was given 0.5 mg. of histamine hydrochloride subcutaneously. The gastric secretions were then completely removed every 20 minutes for one hour. The patients were cautioned not to swallow any saliva during the time the tube was in place. The volume, pH, and rennet activity were determined on each specimen. The pH of the specimens varied between 7.2 and 8.6. There was practically no rennin in any of the samples.

The patients have been divided into three groups. Group I is made up of patients who were in relapse and had received no hematopoietic medication for at least 3 months. The patients in Group II had had some type of medication but the red blood cell counts were not normal; included in this group are 18 patients who were in blood relapse but who were excluded from the first group because they had recently received medication, such as iron or some oral liver preparation. All of the patients in Group III had been on medication and their red blood cell counts were normal.

*From the Lilly Laboratories for Clinical Research, Indianapolis City Hospital, and The Department of Medicine, Indiana University School of Medicine.
Submitted June 3, 1936.

Table I shows the average findings of these three groups in addition to those of 18 normal individuals and of 38 patients having anacidity not associated with pernicious anemia. Before being grouped as easy or hard to maintain the patients were previously or have subsequently been followed for at least one year. Those patients able to maintain normal red blood cell counts while receiving daily 3 vials of powdered liver extract or 12 capsules of 'Extralin' (Liver-Stomach Concentrate, Lilly), or less, were classified as easy to maintain.

RESULTS

There were 58 untreated patients in Group I. Two of these patients were examined in two different relapses, making a total of 60 examinations. The volume of gastric juice per 60 minutes varied between 1 c.c. and 63 c.c., averaging 17.9 c.c. These values agree very closely with those of Goldhamer, as does the average secretion (136.4 c.c.) of the normal individuals. Examination of Chart I shows that while the patients having red blood cell counts below 1.50 million had the lowest average (13.8 c.c.) volume of gastric juice, there is no direct relationship between the volumes and the red blood cell counts. The average value for the 35 patients with red blood cell counts below 2.00 million was 17.3 c.c., while the average for the 25 patients with red blood cell counts above 2.00 million was 18.9 c.c. However, the patients with red blood cell counts below 2.00 million had a distinctly greater average age.

In this group the patients having only early cord changes had an average 60-minute volume of 18.4 c.c., while those with moderate to advanced cord symptoms had only 16.4 c.c. Twenty-four patients' red blood cell counts could be maintained at normal levels while taking medication by mouth. Their average 60-minute secretion was 22.7 c.c., as compared with 16.5 c.c. for the 14 patients who were hard to maintain. The most striking variation in the average volumes of gastric juice was, however, in the various age groups. Examination of Table II shows that in Group I there was a progressive decrease in average volumes with increase in age. There was a tendency for the older patients to have lower red blood cell counts, but when a total of 166 patients in relapse was studied, as to age and initial red blood cell count, this relationship was not evident.

Three patients in Group I are of especial interest. The first was seen in October, 1933, when the red blood cell count was 3.60 million and the hemoglobin 66 per cent. At that time the 60-minute volume of gastric juice was 11 c.c. The patient took 12 capsules of

'Extralin' daily until December, 1933, and then discontinued the medication. By July 30, 1935, the red blood cell count was 1.72 million and the hemoglobin 46 per cent. The hourly gastric secretion was then 7 c.c. The second patient (age 76) on April 7, 1933, had a red blood cell count of 1.45 million, hemoglobin of 38 per cent, and gastric secretion of 7 c.c. per hour. She received medication by mouth and injection up until August, 1934, and then voluntarily discontinued it. By March 19, 1936, the red blood cell count was down to 1.21 million and the gastric secretion was 8 c.c. per hour. The third patient first entered the hospital on January 15, 1935, when the red blood cell

count was 0.5 million and the hemoglobin 12.2 per cent. Marked generalized arteriosclerosis was present and the patient was in severe cardiac failure. Following transfusion and liver extract administered intravenously the patient showed a marked improvement. On February 2, 1935, the red blood cell count was 2.43 million, hemoglobin 50 per cent, and weight 129 pounds. The total secretion of gastric juice for one hour was only 1 c.c. on that day. On March 26, 1935, the patient was discharged from the hospital with a month's supply of liver extract. He did not return again until December 2, 1935, when the red blood cell count was 1.98 million and the hemoglobin 62 per cent. At that time his general condition was good, he weighed 165 pounds and the gastric secretion was 9 c.c. per hour.

In Group II the average volume of the 54 examinations was 31.8 c.c., which is distinctly greater than the average of the untreated patients. However, Tables I and II show that the averages of the various subgroups tend to have the same relationship as in the untreated group.

One patient in this group is particularly interesting. In 1932 the patient was receiving liver extract by mouth and injection, yet the red blood cell count remained in the neighborhood of 4.50 million. At that time the patient was complaining that she could not gain weight (weight was 128 pounds). A urea clearance was 72 per cent of normal and the gastric secretion was only 8 c.c. per hour. Just before re-examination of the gastric juice in 1935, the patient suddenly began to gain weight (up to 140 pounds) and to feel better. The red blood cell count, however, remained at the same level. A urea clearance was repeated at about the same time and it was 97 per cent of normal. The secretion of gastric juice was then 30 c.c. per hour.

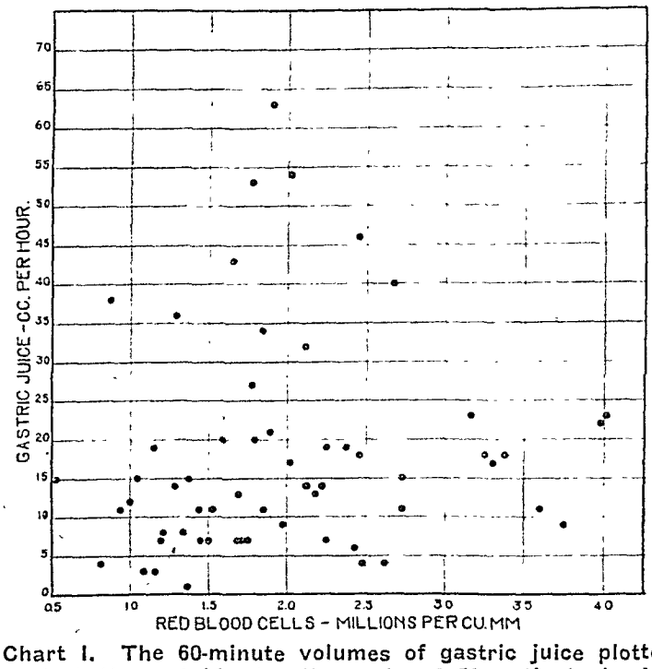

Chart I. The 60-minute volumes of gastric juice plotted against the red blood cell counts of 58 patients having pernicious anemia in relapse.

The *average values* of the 46 examinations in the 44 treated patients (Group III) are still higher, the average being 41.3 c.c., which is practically identical

with the average for the 38 examinations in patients with anacidity not associated with pernicious anemia. The findings as to central nervous system involvement and age in the two preceding groups are substantiated by this group. However, the 15 patients whose red blood cell counts were difficult to maintain at normal levels have a distinctly higher average than those whose blood could be maintained by oral therapy. This can be explained by the fact that the 28 patients with normal red blood cell counts who had received medication by injection averaged 47.8 c.c. of gastric juice per hour while the 16 patients who had received only oral therapy averaged 27.6 c.c. Only 5 of the patients in the easily maintained group had recently received intramuscular liver therapy, but all of the patients whose blood was difficult to maintain had received liver extract by injection.

The *effect of treatment on the volume of gastric juice* is brought out even more forsibly when the small group of patients is studied who were examined when the red blood cell count was below normal and reexamined after the blood improved. Twelve patients who were examined before and after oral therapy showed an average increase of 2.3 c.c., while the average increase in 17 patients after parenteral therapy was 15.7 c.c. The increase following parenteral therapy was more marked in the younger patients, but in all age groups there was a greater increase after parenteral therapy than after oral. The fact that 4 of the patients who showed definite increases in volume of gastric juice after parenteral therapy had relapses of the blood soon after returning to oral therapy, indicates that if this increase is associated with an increase in intrinsic factor it is not long sustained after discontinuing the parenteral therapy. Two patients whose volumes of gastric juice while receiving parenteral therapy were 88 c.c. and 67 c.c., respectively, have subsequently maintained normal red blood cell counts on oral therapy. Their volumes of gastric juice are now 64 c.c. and 44 c.c. per hour, respectively.

CONCLUSIONS

It would seem that the volume of gastric juice secreted after histamine stimulation by a patient having pernicious anemia is influenced by the general condition of the patient, the red blood cell level, the extent of central nervous system involvement, and the type of therapy the patient has received. Although there seemed to be no direct relationship between the volume of gastric juice and the red blood cell level at the time of relapse, the patients with lower red blood cell counts tended to have smaller volumes of gastric juice. The age of the patient appeared to have a more definite relationship to the volume of gastric juice, there being a progressive decrease in average secretion with increase in age. The patients having signs and symptoms of more advanced central nervous system involvement had a slightly lower average volume of gastric juice than did the patients having only minor involvement. The patients in relapse had distinctly lower 60-minute volumes than those patients under treatment. In addition, the type of therapy influenced the volume of gastric juice. In all the age groups the average secretions of the patients receiving liver extract by injection were higher than those of the patients receiving only oral therapy.

Studies on the Chemical Nature of the Interaction Between the Intrinsic and Extrinsic Antianemic Factors Upon Incubation of Liver Extract and Normal Gastric Juice*

By

O. M. HELMER, Ph.D.

and

CHARLES P. EMERSON, Jr., B.S.

INDIANAPOLIS, INDIANA

EVIDENCE that liver substance is a potent source of the antianemic extrinsic factor of Castle has been brought out through the work of Reimann (1), Walden and Clowes (2), Helmer, Fouts and Zerfas (3), and others. Helmer, *et al* showed that daily subminimal doses of Liver Extract No. 343 (material derived from 100 grams of liver) after incubation at 40° C. with 100 c.c. of normal gastric juice produced maximum reticulocyte responses and marked clinical improvement in patients with pernicious anemia in relapse.

Therefore, since liver extract affords a readily available and fairly uniform source of extrinsic factor, we thought it would be of interest to determine whether a chemical change could be demonstrated when liver extract was incubated with normal gastric juice. Incubations were carried out under the same quantitative conditions used in successful clinical experiments; that is, one vial of Liver Extract No. 343 incubated with 100 c.c. of normal gastric juice. The components

of liver extract that were studied were the amino nitrogen content, the acidity with the amino groups suppressed, and the soluble nitrogen content after precipitation with trichloracetic acid.

EXPERIMENTAL

The gastric juice used in these experiments was obtained from young, healthy adults after histamine stimulation. The aqueous solution of liver extract was prepared by shaking Liver Extract No. 343 in water, to which were added a few drops of toluene as a preservative, the proportions being adjusted so that 25 c.c. of the solution represented the soluble fraction of the amount of liver extract derived from 100 grams of whole liver (4.5 grams of powder).

The same incubation technique was employed for each experiment. The incubations were carried out in stoppered test tubes of appropriate size suspended in a water bath which was maintained at 40° C. The incubation mixtures consisted of one part of liver extract solution, four parts of gastric juice, and one part of HCl or NaOH solution, the proportions of the latter being calculated from a previously prepared titration curve of liver extract in such a manner as to fix the pH of one incubation mixture at 2.0, a second at 5.6, and a third at 8.0. The incubation time in each case was 3½ hours.

The study of the proteolytic action of normal gastric juice on liver at pH 2.0, 5.6 and 8.0 involved the following experiments:

1. Titration to a phenolphthalein end-point of 5 c.c. of each incubated mixture following the addition of 25 c.c. of 40 per cent formaldehyde, which was found experimentally to be sufficient to repress all amino groups. The control in this experiment was conducted by pipetting 5 c.c. portions into formaldehyde immediately after mixing the gastric juice and the liver extract solution. Any difference between the acidity of a sample and its control may be interpreted as measuring a liberation of carboxyl groups in incubation. Ten drops of 1 per cent phenolphthalein were used as an indicator and the titration performed in such a way that a direct color match was obtained between each incubated sample and its control. (Table I).

2. Determination by the manometric method of Van-Slyke (5) of the amino nitrogen content of the incubated mixtures and their controls, which consisted of mixtures containing HCl in place of gastric juice. An additional control consisting of pepsin (U. S. P. 1:3000) made up to contain 5 mg. of pepsin per c.c. of 0.1 N HCl was also utilized. These determinations were performed on 5 c.c. of a 4/25 dilution of the incubated mixtures. (Table II).

3. Determination of the nitrogen contained in the non-precipitated fraction of the incubated mixtures after treatment with an equal volume of 10 per cent trichloracetic acid, and, for controls, determination of the non-precipitated nitrogen of a portion of the same mixtures treated with trichloracetic acid immediately after mixing the gastric juice and the liver extract solution. The mixtures containing the trichloracetic acid were allowed to stand 12 hours in a refrigerator before they were filtered. The nitrogen determinations, performed by the manometic

method of VanSlyke (6), were made on 1 c.c. quantities of filtrate. (Table III).

RESULTS

As is evident from Table I, the only effect which may be interpreted as indicating a liberation of carboxyl groups occurred at pH 2, and, expressed quantitatively, it amounted to 0.24 milliequivalents. These figures were paralleled by the results of the amino nitrogen experiments (Table II), which indicated a liberation of 0.24 milliequivalents of amino nitrogen at pH 2 and only very small changes at pH 5.6 and 8.0. These phenomena occurring at pH 2 are felt to be explained adequately on the basis of the pepsin-HCl control experiment (Table II), the results of which indicated a change in amino nitrogen due to pepsin of 0.401 milliequivalents.

As shown in Table III, no change greater than the experimental error occurred in soluble nitrogen not precipitated by trichloracetic acid as a result of incubating liver extract and gastric juice at pH 2.0, 5.6 or 8.0 (Table III).

In addition to the above experiments, an experiment was performed with gastric juice from which all of the pepsin and rennin had been removed by treatment with Lloyd's reagent. Helmer and Fouts (7) have found that gastric juice so treated still contains the intrinsic factor of Castle. In the experiments using this pepsin-free intrinsic factor, no change in the amino nitrogen was obtained even when the incubation was carried out at pH 2.0.

DISCUSSION

Incubation together in vitro of the intrinsic and extrinsic anti-anemic factors, the result of which is presumably production of a material clinically active when fed to patients with pernicious anemia, effects no appreciable change that we have been able to measure in the content of carboxyl groups, amino nitrogen, or nitrogenous substances which are not precipitated by trichloracetic acid. Whether a change occurs which falls into the category of the chemical processes studied but smaller than our methods could elicit, or whether the nature of the phenomenon renders it not amenable to the chemical methods employed, is a matter for future study. There is the further possibility that some other biochemical factor, or factors, in addition to the one occurring in gastric juice, may be required for the formation of the final anti-anemic principle, particularly since the hemopoietic factor of the liver is heat-stable, whereas substances produced by the interaction of normal gastric juice and extrinsic factor are destroyed by boiling for five minutes. Furthermore, the antianemic principle of liver is effective when administered by mouth or parenterally, while, as yet, an effective parenteral preparation from the interaction of gastric juice with liver extract has not been made.

SUMMARY

Attempts have been made to determine the chemical change occurring as a result of incubation together of liver extract and normal gastric juice at pH 2.0, 5.6 and 8.0. The chemical constituents of liver extract which were studied were the carboxyl groups, amino nitrogen, and soluble nitrogen after precipitation with trichloracetic acid.

No significant chemical changes were noted in this series of experiments except for those associated with a slight proteolytic effect at pH 2.0, attributable to peptic activity.

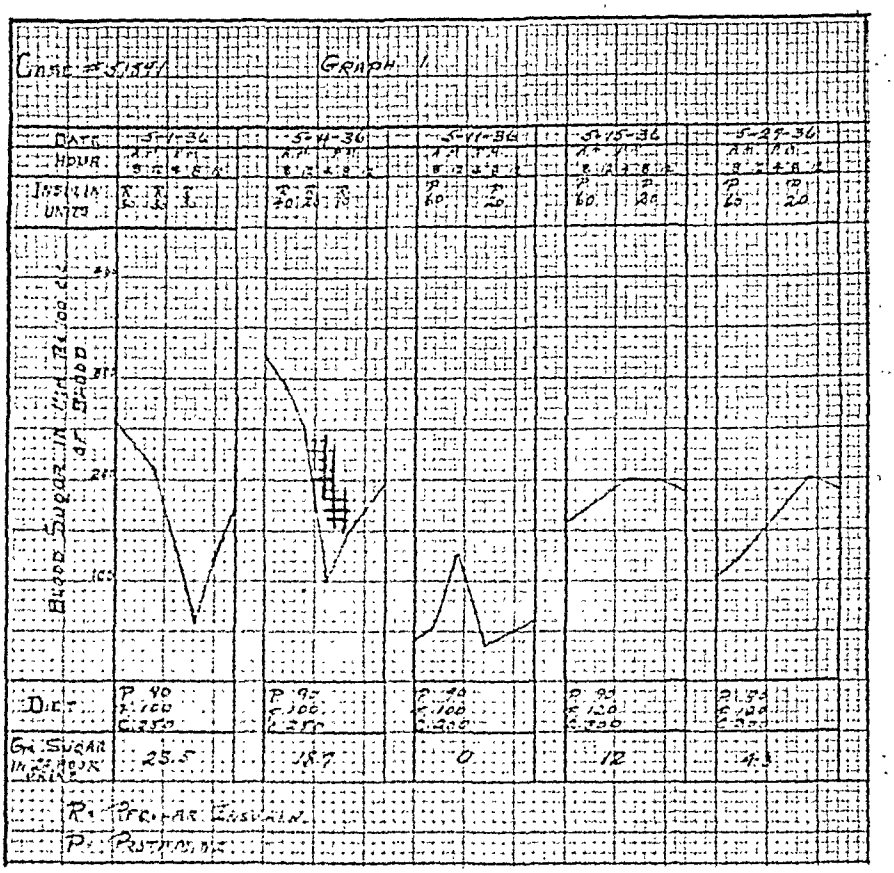
SECTION III—*Nutrition*

Protamine Insulin in the Treatment of Diabetes



By

HARRY G. JACOBI, M.D.*

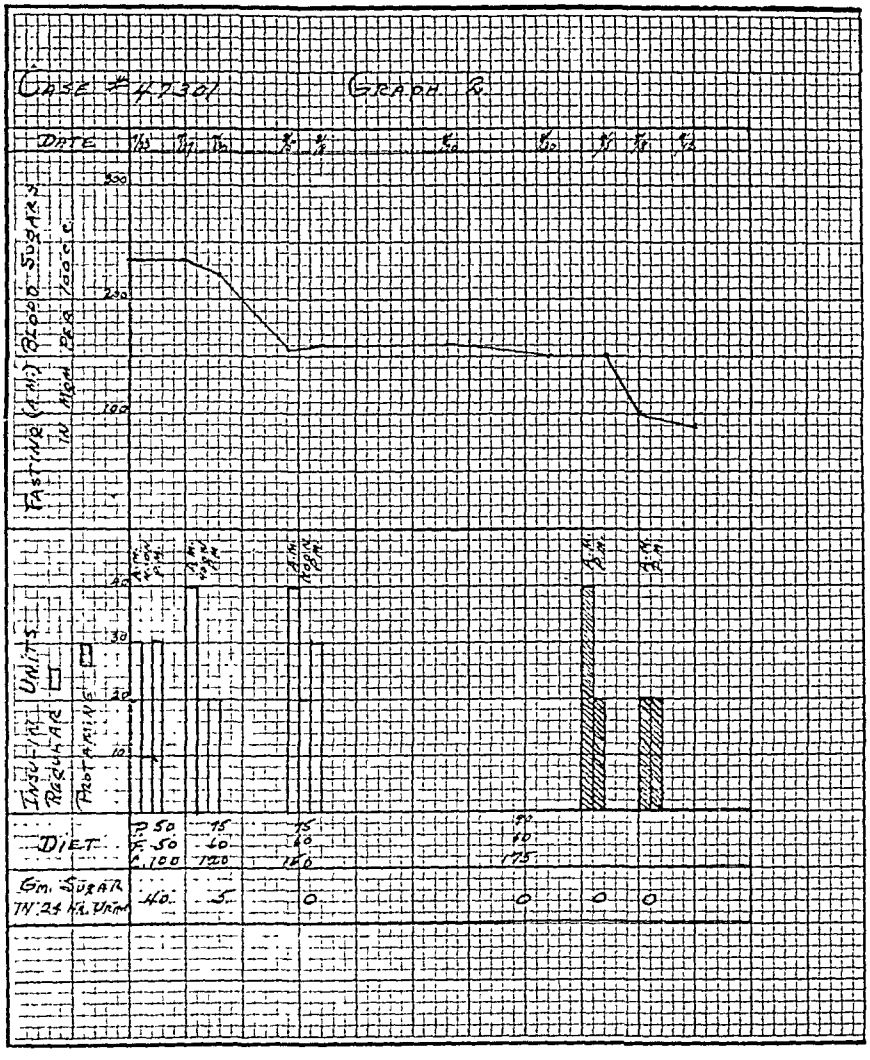
NEW YORK, NEW YORK

PROTAMINE insulin is the precipitate formed by the action of insulin hydrochloride with monoprotamine compounds. It was first introduced by a group of Danish investigators (1), who were searching for a preparation which would give a more sustained lowering of the blood sugar than that obtained by the use of regular insulin. The protamine insulinate resulting from this precipitation, after being properly buffered, was found to be relatively insoluble in tissue fluids, causing the insulin to be liberated slowly and over a prolonged period of time. From our experience and from the reports (2) that have appeared in the short period of time, one gets the impression that this preparation if used wisely, may eventually prove to

*Associate Attending Physician, Lenox Hill Hospital.
Submitted November 11, 1936.

Case 1 (Graph 1) illustrates a moderately severe diabetic whose blood sugar showed marked fluctuations in spite of moderately large doses of regular insulin. The high calorie intake was necessary for the well being of the patient, who complained bitterly about the fact that he was constantly hungry. It will be noted that after a period of one week with the protamine insulin, these wide fluctuations in the blood sugar were considerably diminished and as time went on less protamine insulin became necessary for the control of these fluctuations. This is a representative example of the response of a diabetic patient where the protamine insulin is administered as two doses, one at 8 a.m. and the other at 8 p.m., allowing about two-thirds of the total insulin in the morning dose and one-third in the evening.

be a great advancement in the treatment of diabetes. On the other hand, its use without care or definite knowledge of its action, may produce harmful results and discredit the useful purpose for which it was intended.



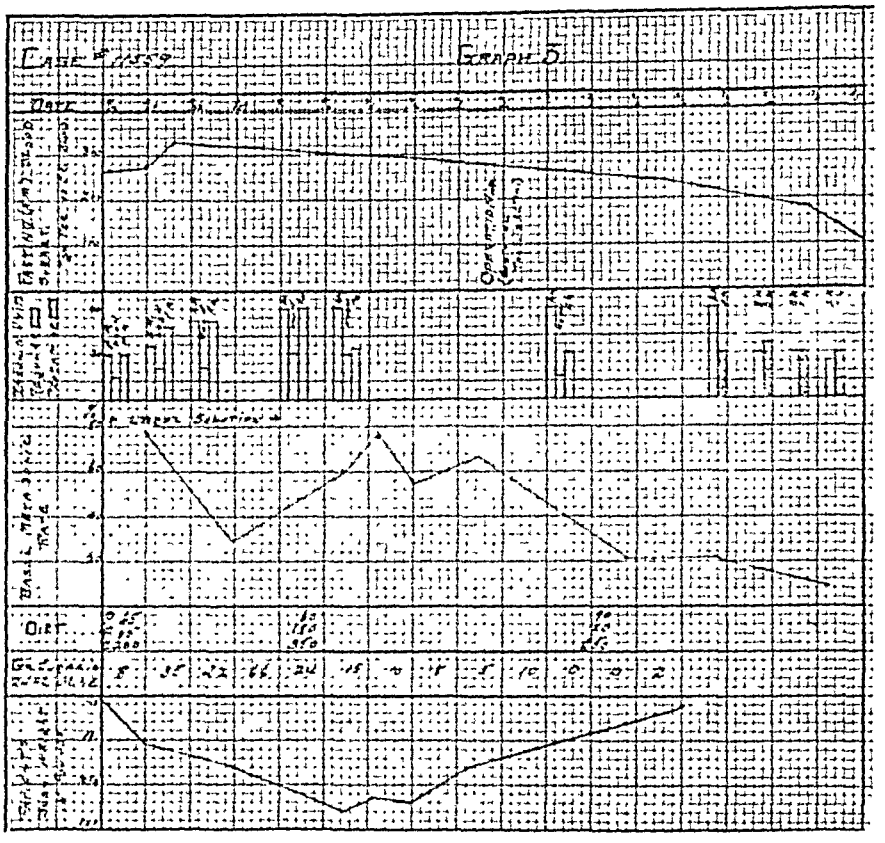
The new preparation as supplied for clinical trial, consists of a small vial containing the protamine to be added to 5 c.c. of U-50 insulin, thus resulting in a U-40 mixture. The solution is shaken thoroughly before each injection and administered subcutaneously. It is not to be used intravenously. When first introduced it was believed that this preparation remained stable for only three or four days and then had to be discarded if not completely utilized at the end of this period. Since then, further investigation has shown that the protamine insulin can remain effective for a period of four weeks.

Action of Protamine Insulin. When a dose of the protamine insulin, equivalent to a diabetic's usual insulin requirement, is injected into such a patient no effect is noted until four to six hours have elapsed. If food is withheld, hypoglycemia will set in at about the ninth hour and this state will continue up to about the thirty-ninth hour, producing usually the train of symptoms either of those associated with hypoglycemia or those associated with acidosis and impending coma.

Indications and Contra-Indications for Its Use. It stands to reason that any preparation having such a marked and prolonged effect, can produce a great deal of trouble if not properly administered. Likewise its use can be greatly discredited by its injudicious employment.

What the medical practitioner is anxious to learn is the exact type of case where this preparation may be of greater benefit than the regular insulin. As far as our experience permits us to judge at the present time, any case of diabetes which in spite of proper diet and adequate doses of regular insulin, shows marked fluctuations in the blood sugar with or without episodes of hypoglycemic reactions, constitutes the ideal indication for the use of the protamine insulin.

After considerable skill is obtained in the use of this preparation, the group of selective cases may be



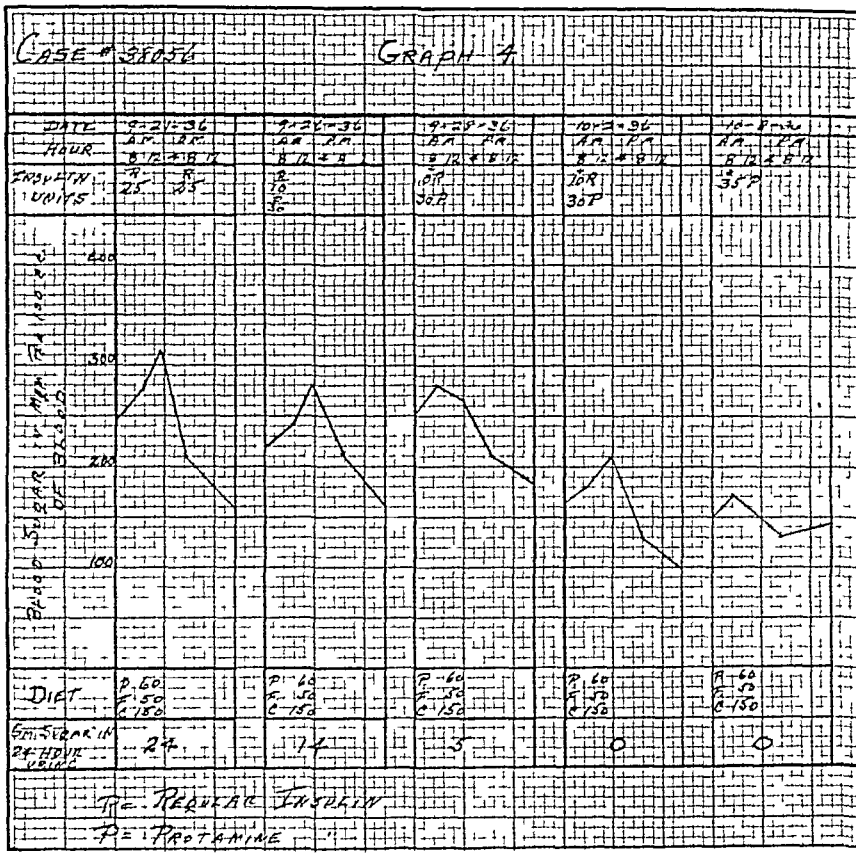
Case 2 (Graph 2) illustrates the case of a mild diabetic whose fasting blood sugar continued to remain elevated although he was sugar free. This condition was very easily corrected by changing to the protamine insulin, using a much smaller dose than that of the regular insulin. On a diet of P. 75 F. 60 C. 120 and regular insulin of 90 units he still persisted in showing a considerable hyperglycemia. Compare this with the increased diet of P. 90 F. 60 C. 175 and an intake of only 40 units of protamine insulin with the resultant disappearance of the persistent hyperglycemia. This shows an example of the procedure similar to that used in Case 1, but where the indication is not as urgent.

enlarged to include the average case of diabetes requiring insulin, where it is desired to obtain a more even blood sugar level during the twenty-four period, or where it is desired to diminish the amount of insulin, the frequency of injections, or both.

It must always be remembered that the protamine insulin has a delayed reaction-time and also that its action when once initiated in reducing the blood sugar continues to do so, over a much longer period than the regular insulin. This action immediately excludes cases of acidosis and impending coma, where quick action is demanded. Likewise new diabetic patients, about whom no observations are obtainable with the regular insulin, should not receive the protamine insulin as an initial method of treatment.

Calculation of Diet and Protamine Insulin Requirement. A practical way of calculating the diet for a patient who is to receive the protamine insulin may be briefly stated as follows: Allow one gram of protein and two and a half grams carbohydrate per kilo of body weight. Enough fat is then added to bring the caloric intake to the required amount. The carbohydrate is so distributed that one-fifth is received for breakfast, and two-fifths each for lunch and dinner. The diet used in Hagedorn's original cases, however, averaged only about 100 Gm. of carbohydrates which were divided into 40% each for breakfast and lunch, and 20% for dinner.

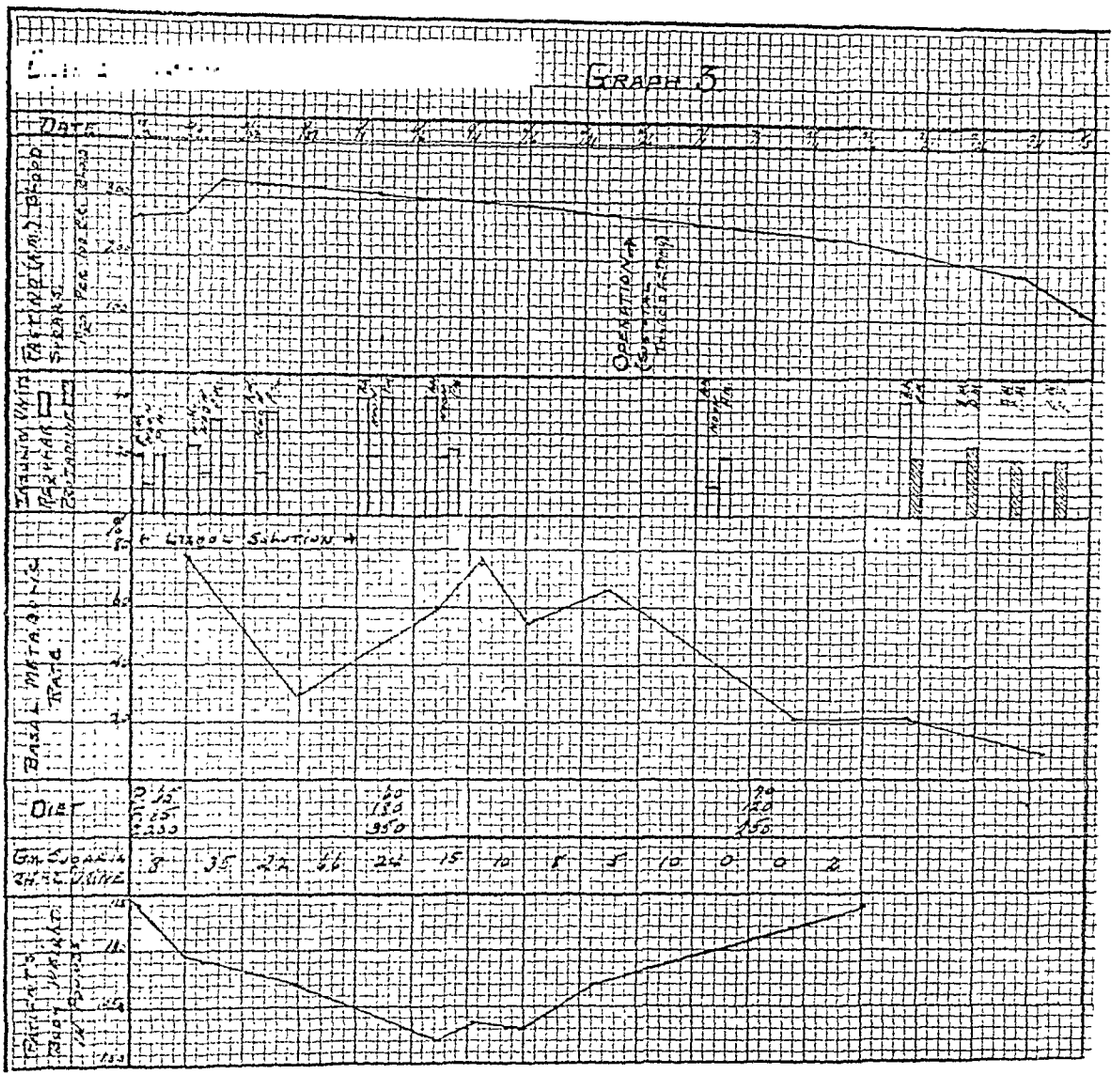
Regarding the actual calculation of the amount of protamine insulin necessary in a given case, one must



Case 3 (Graph 3) shows a moderately severe diabetes complicated by an attack of hyperthyroidism, with the control of the hyperthyroidism by thyroidectomy, marked fluctuation in the blood sugar persisted, and the usual dose of regular insulin proved inadequate. Instead of decreasing the diet which would have been distinctly harmful to the patient, we decided to replace some of the regular insulin with the protamine. This was carried out by giving the larger dose of regular insulin at 8 a.m. and the smaller dose of protamine insulin as the 6 p.m. dose. The improvement in the sugar tolerance was so excellent after a period of this regime that the dosage was eventually reduced to 15 units of regular insulin in the morning and 20 units of protamine insulin at night with complete control of the diabetes. This case follows the procedure originally advocated by Hagedorn and his associates.

always remember that when protamine insulin is used, the calculations that are made are in reality operable over a period of seventy-two hours. Changes in the dose of protamine are not reflected in the blood sugar, or the morning urine, on the day the change is made. For this reason, one must expect some glycosuria for the first few days after the commencement of the protamine insulin therapy.

Several methods of procedure have been followed by different groups of investigators in regard to the amount and time of administration of the protamine insulin and it is my purpose to mention these methods and show their action by means of case illustrations. (1) The method employed by the original investigators consists of giving a dose of regular insulin at 8 a.m. and protamine at 6 p.m. The a.m. dose of regular insulin is about twice that of the p.m. dose of protamine insulin. Blood sugar determinations are made at 7-11-2-5-10, the micro method of Folin (3) being used for this purpose. Daily qualitative tests for urine sugar are made at intervals of two to three hours from 6:30 a.m. to 9:30 p.m. and the ammonia content of the urine determined for the twenty-four period as an indication of fluctuations in the acidosis. The total amount of insulin used during the twenty-four period is increased or decreased as clinical and laboratory indications arise. (2) The method of giving protamine insulin in the morning and regular insulin in the evening. (3) Regular insulin before breakfast and supper and protamine at bed time (10 p.m.). (4) The method of giving both doses as protamine insulin, one at 8 a.m. and one at 8 p.m. (5) The method of using one dose of protamine insulin in the morning, supplemented by a dose of regular insulin administered at the same time but at a different site of injection.



We have had fairly good results with the following procedure and I shall attempt to outline this in as practical a way as possible. We allow a dosage of protamine insulin equivalent to about seventy per cent of the calculated regular insulin requirement that has been given to the particular case at the time. This is administered as one dose about one hour before breakfast. For the first four to seven days of this change from the regular insulin to the protamine insulin, an

Case 4 (Graph 4) represents the procedure which we feel is most ideal for employment in making changes from regular to protamine insulin therapy. The number of injections is eventually reduced to one during the twenty-four hour period and the hyperglycemia and glycosuria kept under better control.

additional dose of the regular insulin equivalent to the remaining thirty per cent of the original insulin intake, is also given an hour before breakfast, using a separate syringe and a different site of injection. If after this four to seven day period, the morning urine fails to show sugar the regular insulin is discontinued. If hypoglycemic reactions have occurred during the night or in the early morning, the dose of the protamine is too large and should be reduced. If, on the other hand, sugar continues to be present in the morning urine, either the dose of the protamine insulin should be increased or the administration of the supplemental dose of regular insulin should be continued. The rate of increase or decrease of protamine insulin should never be more than five units at a time. It is also advisable, whenever possible, to do several blood sugars during the day especially before each meal, in order to have a fairly good idea as to the glycemic response to the treatment. If the proper dose cannot be arrived at to control the morning glycosuria without precipitating hypoglycemic reactions, then the small supplemental dose of regular insulin should be given over a longer period of time instead of increasing the dose of protamine. Emphasis must again be made that this dose of regular insulin is made as a separate injection, otherwise it will be precipitated by the mono-protamine and increase the effect of the protamine insulin.

Factors Influencing the Blood Sugar Level. It must be emphasized at this point that in all cases that fail to respond favorably to regular insulin therapy, a thorough search must be made to attempt to determine whether there are any additional factors responsible for the difficulty. I am, particularly stressing this point at this part of my presentation, for these same factors may act in exactly the same way with protamine insulin, perhaps in an even more exaggerated form and eventually lead to confusion and unwarranted discrediting of this preparation. First: An accurate consideration of the amount of physical and nervous energy expended by the patient is of utmost importance. It is not an uncommon experience to the careful observer to meet a case of diabetes which shows glycosuria when completely at rest and hypoglycemia on another day when the patient is especially active physically. Likewise the effect of nervous strain may produce similar results. In other words proper allowance should be made for additional physical or nervous expenditures of energy in the diabetic patient either by increasing the caloric intake for that period of additional activity or by reducing the amount of insulin allowed. This fundamental fact is very often lost sight of and may cause

Case 3 (Graph 3) shows a moderately severe diabetes complicated by an attack of hyperthyroidism, with the control of the hyperthyroidism by thyroidectomy, marked fluctuation in the blood sugar persisted, and the usual dose of regular insulin proved inadequate. Instead of decreasing the diet which would have been distinctly harmful to the patient, we decided to replace some of the regular insulin with the protamine. This was carried out by giving the larger dose of regular insulin at 8 a.m. and the smaller dose of protamine insulin as the 6 p.m. dose. The improvement in the sugar tolerance was so excellent after a period of this regime that the dosage was eventually reduced to 15 units of regular insulin in the morning and 20 units of protamine insulin at night with complete control of the diabetes. This case follows the procedure originally advocated by Hagedorn and his associates.

always remember that when protamine insulin is used, the calculations that are made are in reality operable over a period of seventy-two hours. Changes in the dose of protamine are not reflected in the blood sugar, or the morning urine, on the day the change is made. For this reason, one must expect some glycosuria for the first few days after the commencement of the protamine insulin therapy.

Several methods of procedure have been followed by different groups of investigators in regard to the amount and time of administration of the protamine insulin and it is my purpose to mention these methods and show their action by means of case illustrations. (1) The method employed by the original investigators consists of giving a dose of regular insulin at 8 a.m. and protamine at 6 p.m. The a.m. dose of regular insulin is about twice that of the p.m. dose of protamine insulin. Blood sugar determinations are made at 7-11-2-5-10, the micro method of Folin (3) being used for this purpose. Daily qualitative tests for urine sugar are made at intervals of two to three hours from 6:30 a.m. to 9:30 p.m. and the ammonia content of the urine determined for the twenty-four period as an indication of fluctuations in the acidosis. The total amount of insulin used during the twenty-four period is increased or decreased as clinical and laboratory indications arise. (2) The method of giving protamine insulin in the morning and regular insulin in the evening. (3) Regular insulin before breakfast and supper and protamine at bed time (10 p.m.). (4) The method of giving both doses as protamine insulin, one at 8 a.m. and one at 8 p.m. (5) The method of using one dose of protamine insulin in the morning, supplemented by a dose of regular insulin administered at the same time but at a different site of injection.

We have had fairly good results with the following procedure and I shall attempt to outline this in as practical a way as possible. We allow a dosage of protamine insulin equivalent to about seventy per cent of the calculated regular insulin requirement that has been given to the particular case at the time. This is administered as one dose about one hour before breakfast. For the first four to seven days of this change from the regular insulin to the protamine insulin, an

about 18 to 20 Gm. of sugar in the 24 hour urine specimen. The carbohydrate intake was then reduced from 250 Gm. to 200 Gm. with the same amount of insulin, without any evidence of checking the marked fluctuations in the blood sugar. It was then decided to use protamine insulin. His diet remained unchanged at P. 90 F. 100 C. 200 and he received protamine insulin 60 units at 8 a.m. and 20 units at 8 p.m. After four days of this regime, the blood sugar determinations before each meal had decreased to 52 mg., 125 mg. and 43 mg. and the urine negative. The following day the patient showed signs of insulin shock with a blood sugar of 34 mg. This was controlled without any difficulty. Inasmuch as the patient complained of being hungry most of the time on the diet allowed, it was decided to increase the diet rather than decrease the protamine insulin. Patient received P. 90 F. 120 C. 300 with 60 units of protamine at 8 a.m. and 20 units at 8 p.m. There were no marked fluctuations in the blood sugar noted any further and blood sugars before each meal on May 27 showed 129 mg., 166 mg. and 200 mg. respectively.

Case 2. (Graph 2). Patient was a 58 year old German sailor who developed a broncho-pneumonia, and in addition had a blood sugar of 235 mg. per 100 c.c. of blood and a CO_2 combining power of the blood plasma of 40 vol. % with 40 Gm. of sugar in the urine. The patient had been unaware of the existance of the diabetes. He was placed on a diet of P. 50 F. 50 C. 100 with regular insulin 30-10-30 (7/23/36). After four days a check revealed a fasting sugar of 234 mg. per 100 c.c. of blood with 5 Gm. of sugar in the urine. It was then decided to change the regular insulin administration to 40-20-20. After an additional seven days on this treatment the fasting blood sugar was still 222 mg. Another increase in the regular insulin was then made, so that patient was receiving 40-20-30 units and after a few days his urine became sugar free. It was then a question of increasing his diet and also of the convenience of this patient's receiving three injections of regular insulin a day after leaving the hospital. We felt that the use of protamine insulin might be of considerable help. The patient's diet was accordingly increased to P. 90 F. 60 C. 175 and protamine insulin given 40 units in a.m. and 20 units in p.m. After six days of this regime the patient reported that he felt exceptionally well, and his fasting blood sugar was 100 mg. with no sugar in the urine. The protamine insulin was accordingly reduced to 20 units in a.m. and 20 units in p.m. Thus this patient who on a diet of P. 75 F. 60 C. 120 and 90 units of regular insulin a day, still persisted in showing a considerable hyperglycemia, became normal with the use of only 40 units of protamine insulin a day, in spite of the fact that his diet was increased to P. 90 F. 60 C. 175.

Case 3. (Graph 3). This case is of particular interest as demonstrating the marked disturbance that can take place in the carbohydrate metabolism of a diabetic patient with the onset of hyperthyroidism. The patient was a 31 year old male with a diabetic history dating back twelve years. It is of interest to note that at that time I did a basal metabolism test and found it to be + 5%. Since that time the patient had been getting along on a fairly liberal diet with 20 units of regular insulin twice a day. Five months prior to the present admission to the hospital, patient began to complain of nervousness, palpitation, loss of weight and fatigue. His weight loss during the five months period was thirty-five pounds. On admission to the hospital his weight was 118 lbs. Fasting blood sugar 263 mg. per 100 c.c. of blood, and B. M. R. + 77%. He was given 5 minims of Lugol's solution three times a day and a diet of P. 90 F. 150 C. 250 with insulin 30-15-30. After ten days the B. M. R. dropped to + 30% but his weight had decreased further to 107 lbs. It was therefore decided to increase the caloric intake and also the amount of regular insulin, in order to stop the marked weight loss. Accordingly his diet was increased to P. 60 F. 180 C. 350 with regular insulin 40-20-25. In spite of this therapy the fasting blood sugar (6-3-36) remained elevated at 312 mg. and the weight showed a further decrease to 103½ lbs. His B. M. R. had risen to + 60% and his condition was considered very unfavorable. It was decided after considerable consultation, to attempt a subtotal thyroidectomy on the patient. This was performed on 6-25-36 and was effective in lowering the B. M. R. and eliminating most of the hyperthyroid symptoms. After a stormy convalescence, the control of the diabetes was again attempted. Accordingly, the patient was given a diet of P. 70 F. 120 C. 250 with regular insulin 40-10-20 units. The patient however continued to have a hyperglycemia (244 mg.) and glycosuria. Rather than decrease the diet or increase the dosage of regular insulin, we thought that protamine insulin should be tried. Accordingly the diet was kept the same and the morning dose of 40 units regular insulin was continued, and in addition 20 units protamine insulin allowed at 6 p.m. After two days the patient had an insulin reaction at 2 a.m. and as a result the insulin dosage was further reduced to 20 units regular in a.m. and 30 units protamine at 6 p.m. The patient continued to show marked improvement with absence of hyperglycemia or glycosuria, so that after ten days the insulin was further reduced to 20 units regular in a.m. and 20 units protamine at 6 p.m. The patient's weight had increased to 114 lbs. and he was sent home on the same caloric intake as above with 15 units regular insulin in a.m. and 20 units protamine insulin at night.

Case 4. (Graph 4). Patient was a 78 year old female with a history of diabetes of long standing. At the time of admission to the hospital she was suffering from a rather marked cardiac decompensation. In addition she complained of precordial pain with radiation down the left arm and weakness. The patient had not been receiving insulin prior to admission to the hospital. The blood sugar was 294 mg. per 100 c.c. of blood and CO_2 combining power of the blood plasma 49 vol. %. Her urinary sugar was 24 Gm. during the 24 hours. A diet consisting of P. 60 F. 50 C. 150 was allowed at time of admission with regular insulin Units 25-0-15. After a period of about 10 days (9-21-35) her blood sugar values before each meal were 271 mg., 308 mg. and 228 mg. with sugar excretion reduced to 14 Gm. for the twenty-four hour period. It was then decided to institute protamine insulin therapy rather than increase the regular insulin dosage, or decrease the carbohydrate content of the diet. Accordingly she received 30 units protamine insulin, and 10 units of regular insulin, one hour before breakfast, as separate injections. It is very interesting to note the gradual lowering of the sugar curves done at several day intervals, while on this regime. The last one performed was after the patient had been taking only the protamine insulin as one dose in the morning. Comparison of these different sugar curves shows the striking changes and resultant establishment of the blood sugar on a much lower level and without wide fluctuations during the twenty-four hour period.

DISCUSSION

The treatment of diabetes with protamine insulin opens up new fields of possibilities. With the use of regular insulin the moderate case offers little difficulty. The more severe forms of this disease however often show marked fluctuations in the blood sugar that cannot be controlled without either reducing the carbohydrate intake or administering insulin at more frequent intervals. Because of its prolonged action protamine insulin becomes ideally suited for treating such cases. In doing this one must avoid the error of changing too many factors at any one time or of making too frequent changes. This point cannot be stressed too much.

Thus, when the change is made from regular to protamine insulin, the dietary factor should not be changed at the same time. Likewise a sufficient period must be allowed for observing the effects of this change before attempting additional ones. From a practical point of view it is much better to begin with too small a dose of protamine insulin rather than a too large one. A fairly good idea is usually obtained as to the course of the blood sugar, if three determinations are made, one before each meal about every fourth or fifth day, and the urine examined at varying periods after each of these meals.

SUMMARY

1. Diabetes showing marked fluctuations in the blood sugar, or those cases associated with certain complicating factors, as hyperthyroidism, hepatic enlargement, etc., can be controlled better by protamine insulin than by regular insulin.

2. Cases of diabetes showing a persistent hyperglycemia or where it is desired to diminish the frequency of insulin administration should receive protamine insulin.

3. Protamine insulin should not be used in cases of acidosis or impending coma or those complicated by surgical conditions.

4. Untreated cases of diabetes should not receive protamine insulin as an initial form of treatment.

5. When changing from regular to protamine insulin we have obtained good results by giving 70% of this amount as protamine insulin and the balance as regular insulin, both administered about one hour before breakfast as separate injections.

6. After a period of 4 to 7 days if the morning urine is sugar free, discontinue the dose of regular insulin. If the morning glycosuria persists, increase the protamine insulin.

7. Increases or decreases in protamine insulin should consist of only five units at a time.

8. Too many factors should not be changed at one time, nor should the effected changes be made at too frequent intervals, when using protamine insulin.

The Present Evaluation of Vitamin B_1 Therapy*

By

MARTIN G. VORHAUS, M.D.
NEW YORK, NEW YORK

THIS paper will attempt to evaluate the therapeutic importance of vitamin B_1 up to the present time. By emphasizing the word "present" we come face to face with the fact that we are about to discuss a subject which is still vague, still in the process of emerging from an experimental problem to an accepted clinical concept.

After years of investigation, vitamin B_1 has finally yielded its precise chemical structure and molecular arrangement (1) and, within the past two months, its artificial synthesis has become an accomplished fact (2). The biochemist has made this vitamin available (3) and we, as clinicians, must be prepared to use it with an understanding of its clinical indications and its limitations.

Three questions present themselves:

1. What is the state of vitamin B_1 deficiency in humans?

2. What is the action of vitamin B_1 in the presence of this deficiency? and

3. Why should we use vitamin B_1, clinically, in diseases other than proven B_1 avitaminosis?

We are all familiar with the fact that *beriberi* is due to a vitamin B_1 deficiency. As a matter of fact, it represents a stage of deficiency so marked that death will invariably occur unless large amounts of vitamin B_1 are given. Thus it has been shown, that in severe cases of beriberi, the administration of vitamin B_1 by mouth is often insufficient to prevent death (4). In these cases, intravenous injections are necessary since gastro-intestinal disturbances interfere with adequate vitamin absorption. This is well known to the workers in the Orient, particularly to those who deal with the problem of infantile beriberi (5). It may not be familiar to all in this audience that the second most frequent cause of infant mortality in China, the Philippines and adjacent countries, is infantile beriberi. The vast majority of these infants are borne of beriberi mothers (6). The method of treatment of infantile beriberi has become fairly well standardized. Even before crystalline vitamin B_1 was available, a concentrate of sufficient potency for intramuscular injection was widely used throughout the Orient. The concentrate is known as "tiki-tiki" and in severe cases of infantile beriberi it is given by subcutaneous or intramuscular injections of 1 c.c. every hour for six, eight or even twelve doses. As soon as the response takes place, which usually occurs within a few hours, the infant stops vomiting, there is cessation of convulsions and fluids are retained. Vitamin B_1 is then continued by oral administration.

As well known as beriberi is in the East, just so rarely do we see it here and the diagnosis of a proven case of beriberi merits a report in one of our medical journals (7). In the East, workers in this field also recognize a clinical entity which they describe as

*Read before the Middlesex County (N. J.) Medical Society, October 21, 1936.
Submitted October 26, 1936.

latent or sub-clinical beriberi. By that is meant a state of vitamin B_1 deficiency which is not severe enough to give the classical symptoms of beriberi but which, nevertheless, has a fairly well recognized set of symptoms interfering with normal health. If allowed to continue for a sufficient length of time, true beriberi develops. This state of ill health, the sub-clinical phase of the disease, entirely disappears with administration of vitamin B_1 for a sufficient period of time.

Now, then, if we here in this country were to confine our use of vitamin B_1 to those cases in which its deficiency was sufficiently well marked to be readily recognizable, there would be no point to this paper. This brings us to the third hypothetical question: why should we consider the therapeutic administration of vitamin B_1 in conditions other than proven B_1 avitaminosis. Of course, the answer to this question is based upon the hypothetical assumption that there are states of partial vitamin B_1 deficiency too mild or too recent to be detected as definite entities (8).

In our early work, the problem was to determine how these states could be recognized. No clinical sign, no laboratory test was available so we fell back on the method of trial and error. Through funds furnished by the Carnegie Institution of Washington, D. C., a large amount of crystalline vitamin B_1 was prepared by my chemical associates and with crystalline vitamin B_1 as the only therapeutic agent, we began the study of a controlled series of chosen cases.

Since *polyneuritis* is so typical of true as well as latent beriberi, we studied this group first. All types of neuritis were included in the study group. To date, over two hundred and fifty cases have been followed with varying degrees of improvement; i. e. from partial relief of pain to complete disappearance of all symptoms; in about 90% of cases.

Our results have been substantiated by a number of other investigators (9, 10, 11, 12). Speaking conservatively, then, we can say that vitamin B_1 is an important therapeutic agent in the treatment of neuritis. You will notice that I have not defined the word neuritis and I have done that deliberately, because the results of vitamin B_1 administration are equally good in localized neuritis as they are in polyneuritis; equally beneficial in neuritis of so-called alcoholic origin as in neuritis associated with infection, anemia, pregnancy or that due to other etiological agents. We see in the action of vitamin B_1 in neuritis, a real analogy to the action of iron in all types of secondary anemia. In alcoholic neuritis we can, by the administration of adequate amounts of vitamin B_1, bring about marked improvement or complete disappearance of all symptoms even though there is no change in the alcohol consumption. Careful study of these patients, however, indicates that the alcohol probably does not play a direct part in the production of the neuritis but that these individuals have really been on a vitamin B_1 deficient diet. If these patients continue to ingest an adequate amount of vitamin B_1, there will be no recurrence of their neuritis. In all of these cases, the duration of the symptoms bears a direct relationship to the duration of treatment. Polyneuritis that has been present for from three to six months, will subside after a few weeks of treatment. Polyneuritis of ten or more years' duration may, in a very short period of time, reach a state of marked improvement but complete disappearance of symptoms may not take place even after three or four months of treatment. This is equally true in experimental animals in which two stages of B_1 deficiency—an acute and a chronic stage—are observed (13). The acute stage will disappear quickly and completely on vitamin B_1 and post mortem studies of these cured animals show little or no cellular changes. The chronic stage responds slowly and gradually. Even after the animals appeared cured, clinically, and then were sacrificed, it was possible to demonstrate many types of cellular change in central nervous system and peripheral nerves, varying somewhat for the different species of animal used (14).

The value of vitamin B_1 in *pregnancy* has an important practical significance. The view that pregnancy induces a deficiency state has been expressed by many investigators (15). The occurrence of anemia, the diminution or absence of gastric acidity, the demineralization, the polyneuritis and, perhaps, even the toxemias, all point to a deficiency state. When neuritis occurs in pregnancy, the ingestion of vitamin B_1 is followed by a marked improvement or disappearance of the polyneuritic manifestations (16, 17, 18).

From the clinical point of view, the group of neuritis most often seen are the so-called sciatic, the sacro-iliac and the shoulder girdle neuritides. These cases are frequently associated with areas of focal infection and, as a matter of fact, we have all seen, in occasional patients, a dramatic improvement following the removal of a correlated infected area. Unfortunately, such cures are few in number as compared with the disappointments that have followed the removal of teeth, tonsillectomy and similar procedures. A number of cases in our series have fallen directly into this group and we have attempted to evaluate the benefit from vitamin B_1 therapy regardless of the continued existence of a proven focus of infection. In this group, also, there has been a marked improvement in a large number of cases. It must be freely admitted, however, that there is a considerable proportion of recurrences in these cases of infectious neuritis—recurrences which, apparently, are due to the constant absorption of bacterial toxins. It is not surprising that such a condition prevails in this group. It is surprising, rather, that in the presence of a focus of infection, as marked an improvement as 70% could be noted.

The groups mentioned already are those most frequently observed in clinical practice but there are many others that merit consideration. The first to be included are the cases of neuritis *associated with varying types of anemia* of which, perhaps, the most interesting is the group associated with primary macrocytic anemias. The improvement in the neuritic manifestations of macrocytic anemia has been observed by other investigators as well as ourselves. There is a special problem connected with this group —the problem of dosage and duration of treatment. It seems possible that the clinical paradox of the pernicious anemia patient showing improvement in his blood picture but dying of subacute combined degeneration of the cord may be modified by vitamin B_1 therapy. Further studies are necessary in these cases. Certainly, neuritis associated with secondary anemia usually responds readily.

Among the less common types of neuritis are those associated with *lead poisoning* and other heavy metals and here attention is directed to the arsenical neuritis

occurring during intensive treatment for syphilis. These types of neuritis have been included among our series and show a gratifying response to the use of vitamin B_1 therapy.

We have had the opportunity to study five cases of severe trigeminal neuritis—the so-called *tic douloureux*—all of whom were operated upon and showed recurrences post-operatively. Three of these five have now had complete relief of symptoms; the other two are showing improvement while still taking vitamin B_1.

Recent experiences with *optic neuritis* and auditory neuritis are of interest. Our own series consists of too small and too recent a group to warrant positive statements but some good results have been reported already to me, personally. These two groups offer a very fruitful field for the specialists in these branches of medicine.

We must then summarize our experience in the treatment of all forms of neuritis by vitamin B_1 as one that justifies its use by giving a large percentage of improvement or cessation of symptoms. I want to call to your attention the fact that in practically none of these cases was it possible to say, at the beginning of treatment, that a vitamin B_1 deficiency state surely existed. The value of vitamin B_1 therapy in neuritis is emphasized again and again because, up to the present time, there is no other syndrome in clinical medicine in which we are as sure of its worth except, of course, in true or latent beriberi.

Herpes zoster belongs among the neuropathies frequently seen in clinical practice. The experimental physiologist has studied the possible relationship of vitamin B_1 to the susceptibility of experimental animals to the virus of herpes (19). At the present time, results are inconclusive. We have had the opportunity to study the effect of vitamin B_1 in its relation to the post-herpetic paresthesias and anesthesias and our clinical results suggest a definite beneficial action, namely, a quicker disappearance of the residual symptoms, and a smaller number of cases with persistent anesthesia in the treated cases than in the controlled series.

A recent report in the German literature describes the value of vitamin B complex in the treatment of *mild chorea* (20). We have had no experience with this type of case but I mention it as it is of interest to men in pediatric practice.

Now, we must leave what is fairly well proven and go on to the more hypothetical and, therefore, questionable use of vitamin B_1. Experimentally, in animals, there is a definite relationship between vitamin B_1 and the carbohydrate metabolism. The relationship is a complex one but a careful survey of the vast biochemical studies gives the following data:

1. In dogs, deprivation of vitamin B_1 is followed by an increased blood sugar and the presence of urinary sugar (21). When insulin is given to these animals, the blood sugar level decreases and the urinary sugar disappears but in spite of insulin, the animals go on to death. Careful studies of the blood chemistry of these animals show no significant changes in the nitrogen elements but the carbon dioxide of the blood falls and the lactic acid level increases (22).

2. The rate at which the symptoms and signs of vitamin B_1 deficiency develops in all animals can be influenced by the amount of carbohydrate in the diet, i. e., the larger the amount of carbohydrate ingested the more rapid is the onset of the manifestations of avitaminosis. Death occurs more rapidly in animals on a high carbohydrate diet than in those on a low carbohydrate diet (23).

3. The change in the carbohydrate metabolism in B_1 avitaminosis is a cellular one and has been demonstrated in minced tissue outside of the body. The brains of B_1 deficient pigeons, in vitro, show a lower capacity to take up oxygen than normal pigeons brains (24). In the avitaminotic brain tissue is found increased lactic acid and pyruvic acid. The latter is not found in the normals (25). By adding crystalline vitamin B_1 to the minced avitaminotic brain tissue, the oxygen take up approaches the normal, the lactic acid decreases and the pyruvic acid disappears (26, 27, 28). The ratio between increased oxygen take up and pyruvic acid disappearing was a fixed constant. Recently, increased pyruvic acid was found in the blood of avitaminotic pigeons and rats in large amounts (29). This returns towards normal in animals cured by the administration of vitamin B_1 (30).

So close, then, is this relationship between vitamin B_1 and carbohydrate metabolism, that the state of B_1 deficiency has been referred to as "a chronic carbohydrate poisoning" (31).

In our clinical experiments, we have been studying the effect of vitamin B_1 in cases of known *carbohydrate disturbances* of all degrees and severity (32). Into this group fell cases that were classified as diabetes. In the majority of cases of true diabetes mellitus, we have seen no beneficial effect from the administration of vitamin B_1. I would like to make this more emphatic by stating that we have actually seen an increase in blood sugar and urinary sugar output in some of these patients; so that the question of whether vitamin B_1 brought on an aggravation of the diabetic state may justly be raised. However, a few of our cases showed a startling modification of the carbohydrate disturbance with lowered blood sugars and lowered urinary sugar output. In those patients with disturbance of the carbohydrate metabolism in whom other stigmata of deficiency co-exist such as unexplained obesity, the loss of appetite, polyneuritic manifestations and diminished metabolic rates, we have obtained our best results. These patients fell into the group described by Joslin as "unclassified diabetes." Careful analysis of the marked change in their carbohydrate metabolism after taking vitamin B_1 raises considerable doubt as to whether these patients belong in any diabetic grouping.

It has been proven, experimentally, that vitamin B_1 is of fundamental importance in the carbohydrate metabolism. The confusion as to its clinical use is due to our clinical inability to separate true diabetes mellitus from the other forms. It seems likely that among these other forms are cases of partial vitamin B_1 avitaminosis which is reflected in the carbohydrate disturbance. These cannot, as yet, be separated but chemical studies now under investigation offer the prospect of a solution to this problem. Until these false diabetics can be recognized easily, the use of vitamin B_1 in so-called clinical diabetes is justified only on an experimental basis (33, 34, 35).

Another interesting relationship is that of vitamin B_1 to *metabolism* (36). In dogs on a B_1 deficient diet, the time required for the development of anorexia is

an accurate indication of the rate at which avitaminosis is developing. By forced exercise the time required for anorexia to appear is materially shortened (37). When thyroid is administered to induce hyperthyroidism in these dogs, anorexia develops very rapidly (38). Experiments on pigeons also show a greater vitamin B_1 requirement in hyperthyroidism than under normal conditions (39). In rats, protection against thyroxin poisoning can be accomplished by the administration of vitamin B_1 (40).

It is a justifiable conclusion from these and other studies that the vitamin B_1 requirement of an animal is proportionate to the metabolism of the animal (41). Some recent studies with dinitrophenol show that this drug does not influence the B_1 requirement of the animal but that "the total caloric intake and body weight are the most important factors in determining the vitamin B_1 requirement of the organism (42)."

With this experimental background, we have included for clinical study a group of cases ordinarily classified as *hypothyroidism*. These have a lowered *metabolic rate, usually not lower than minus twenty-four*, a moderate obesity and, yet, show none of the mental stigmata of true hypothyroidism. In several of these patients under observation, the administration of thyroid has been of little or no value. They appear to be cases of lowered general metabolism rather than of thyroid deficiency. The action of vitamin B_1 in these cases is the action of a metabolic stimulant. We are, at present, studying more of these cases and have observed improvement not only in the clinical state but a return of the basal metabolic figures to the normal. Detailed studies of this group will be reported in another paper.

I should like very much to close the discussion of vitamin B_1 therapy at this point but I would be omitting a group of cases in which vitamin B_1, apparently, has some value. These patients complain of *vague gastro-intestinal disturbances* (43) associated with constipation and show unexplained gastro-intestinal hypotonia on X-ray examination. I should like to omit this group of cases because in the literature of pharmaceutical houses this vague syndrome has been over-exploited and over-emphasized. The failure to improve many cases of infantile and adult constipation with the use of vitamin B_1 has served to discredit the value of this important therapeutic agent. Vitamin B_1, as I have said before, is not a constipation cure. There are, unquestionably, some patients in whom constipation results from a vitamin B_1 deficiency state (44) but they represent an extremely small percentage of cases. If vitamin B_1 is to be judged as a therapeutic agent on its response in cases of unexplained constipation, the results are bound to be disappointing.

Up to this point, I have attempted to confine the discussion of the value of vitamin B_1 to fairly well established clinical states. In addition to those states described, there are some obscure and ill-defined clinical entities, characterized usually by one symptom or another, in which vitamin B_1 is indicated but here again a word of caution as to its value must be expressed. I refer particularly to those cases of loss of appetite. Much has been published about the tremendous value of vitamin B_1 in anorexia. It is true that experimentally induced vitamin B_1 deficiency in animals is characterized by a marked loss of appetite. It is also recognized that by feeding vitamin B_1 the appetite promptly returns. This occurs in patients who have a similar deficiency state. However, it is unwise to use as a clinical yardstick the existence of anorexia to justify a prescription for vitamin B_1. This is especially true in children where *anorexia* is too often the result of a psychological problem at home, a behavior characteristic rather than a vitamin B_1 deficiency state. The value of vitamin B_1 in stimulating appetite finds its greater usefulness in the anorexia associated with long standing illnesses or in patients on limited diets for various chronic diseases, and obesity. In such patients the disappearance of anorexia is frequently observed. The next poorly defined state that we will consider for a moment is that characterized by unexplained weakness, and again the same rule applies that has been expressed in relation to loss of appetite. Unexplained weakness is, too often, an early symptom of an early or obscure organic diseased state or, at times, particularly in adults, too often an expression of psychological maladjustment. To expect that the administration of vitamin B_1 will be followed by a return of vigor and energy in many of these patients is to believe in the impossible. Just as in loss of appetite, weakness following convalescence from a serious illness or associated with long continued malnutrition will often disappear with the administration of vitamin B_1.

Throughout this paper, I have repeatedly used two phrases

(1) "adequate amounts of vitamin B_1"; and
(2) "for a long enough period of time"

and I feel that I have come to the point where these phrases must be more explicitly defined. There are available, at the present time, to the physician, many different sources of vitamin B_1. The crystalline material which is made by Merck & Company is available only in small amounts. It is difficult to procure and it is expensive. At the present time, its use should be reserved for those severe cases of vitamin B_1 deficiency that require a large dose in a short period of time and for those cases in which vomiting, diarrhea or extensive gastro-intestinal disease preclude the probability that there will be adequate absorption of vitamin B_1 if given by mouth. In such cases, the administration of from two to ten mgm. as a daily dose may be desirable. In advanced B_1 avitaminosis where the question of death is a pressing possibility, the administration of ten mgm., intravenously, once a day, may be safely used. Within five days, or sooner, an improvement will be noted if the diagnosis of a vitamin B_1 deficiency is correct.

However, such cases represent a very small percentage of those under consideration. For all the rest, vitamin B_1 by mouth will suffice. Here the crystalline product need not be employed, as sufficiently strong vitamin B_1 concentrates are available. The factor of dosage must be determined on the basis of units of vitamin activity. Unfortunately, there is some confusion at present, as two standards are in general use, the first being the Sherman Chase unit and the second being the International unit. 1.3 Sherman Chase units is the equivalent of 1 International unit. In the majority of cases of adults, it is desirable to administer from one to two thousand Sherman Chase units a day. Therefore, it becomes necessary to determine the Sherman Chase unit content of the preparation to be used and I am happy to say that through the cooperation of many of the pharmaceutical houses, the recent

products are all labelled with their vitamin unit content. Preparations in capsule form, containing from two to four hundred units per capsule are available and, thus, by the administration of from three to six capsules a day, an adequate amount of vitamin B_1 can be administered readily. Most of the concentrates on the market contain sizeable amounts of vitamin B_2 and vitamin B_4. It should be emphasized, at this point, that in our first hundred cases the results were obtained with crystalline material in which, therefore, we were certain that we were only using vitamin B_1. In the subsequent larger number of cases now under consideration, we have used the cheaper commercial concentrates and in the same dosage we have not observed any difference in our results, so that the amounts of vitamin B_2 and vitamin B_4 in the preparations that will be widely used, because of their availability and because of their lowered cost, do not seem to play a significant role in the therapeutic results.

The next factor of importance, as we have stressed it again and again in this paper, is the duration of time. How long should a patient take two thousand Sherman Chase units of vitamin B_1 a day before he may expect a result? This is a question which is very important to the physician as well as to the patient. In the light of our present knowledge, we are well aware of some of the factors that complicate this problem. The first, of course, is the duration of the symptoms or the duration of the disease process and, as I have indicated before, a polyneuritis of two or three months duration will respond in a short period of time, usually in three or four weeks. A polyneuritis of five to ten years' duration may not begin to show response for three or four weeks and response may not be marked until twelve or more weeks of treatment. This is frequently so in those cases of disturbance of the carbohydrate metabolism and, in fact, in cases of general lowered metabolism to which I have referred. In such, some improvement is usually noted in four weeks. In our series of cases, if an improvement was not observed in four weeks, it did not occur at all and such a patient would probably not be benefited by continued use of vitamin B_1 for a longer period of time. This is especially true in cases of unexplained anorexia and unexplained weakness. If a vitamin B_1 deficiency is responsible for the loss of appetite or weakness, a response usually occurs within two weeks of treatment on two thousand Sherman Chase units a day, and if after four weeks there has been no improvement, the failure to modify the symptoms is usually a very reliable indication of an inaccurate diagnosis and an inaccurate indication for the use of vitamin B_1 in that particular patient.

There are several other factors that modify the duration of treatment. Experiments have shown that metabolism influences the vitamin B_1 requirement—that in an artifically induced hyperthyroidism, the vitamin B_1 requirement is greater; that in animals on forced exercise, there is also an increase in the need for vitamin B_1 in the tissues. These experiments are useful guides in the interpretation of the problem of how long to give vitamin B_1. In those cases of pregnancy in which it is of use, it is to be given during the entire term of pregnancy. The vitamin B_1 content of the new born infant is directly related to the amount of vitamin B_1 available in the pregnant mother. In this regard, the new born infant responds to vitamin B_1 deprivation and to vitamin B_1 administration in the same way as it does to the deprivation or administration of the hematopoietic substances in the pregnant mother. The analogy is carried further, since vitamin B_1 in excess of the needs of the patient is excreted in the urine (45) as, you will recall, has been demonstrated in the case of the anti-anemic principle (46). Experimentally, it is possible to cure rats and other animals by feeding them human urine from individuals receiving an adequate amount of vitamin B_1 in their diet (47, 48), just as in the same manner it has been possible to effect reticulocytosis by the rectal administration of human urine from normal individuals (49). Large amounts of urine from patients suffering from beriberi have no effect upon the course of vitamin B_1 deficiency in rats.

An interesting observation on the use of vitamin B_1 should be noted at this point. About 20% of all cases of polyneuritis experience an intensification or aggravation of their neuritic pain soon after starting oral treatment. The increased pain is usually noticed in from three to five days from the onset of treatment and is most intense about the seventh day. Thereafter, the pains subside and improvement takes place. The reason for this acute temporary exacerbation is not clear, but it occurs often enough to justify a warning of its occurrence to the patient who is about to commence treatment.

There is, at least, one more question that must be answered before closing and that is, what are the contraindications to the administration of vitamin B_1? Is there such a thing as an overdose—a hypervitaminosis? This question was one of the first that we investigated in our experiments with humans. We administered as high as ninety thousand Sherman Chase units a day to some patients and were unable to observe any harmful effect. We were able to detect large amounts of vitamin B_1 in the urine of individuals on excessive dosage and this seems to be the factor of safety. Similarly, we have had patients who have taken vitamin B_1 daily in dosage of from one to two thousand Sherman Chase units a day, for over two years and we have not observed any untoward effects. The lessons learned from biochemical and physiological experiments with this vitamin indicate that this is what we should expect. Storage of vitamin B_1 within the body has not been demonstrated and it probably does not exist. The action of vitamin B_1 is the action of a catalyst that concerns itself with oxidation of the degradation products of glucolysis.

In vitamin B_1 we have in our hands an important therapeutic substance whose usefulness has not been thoroughly defined. At the present time, we must take the greatest care to confine its clinical use to those entities described in this paper. If we attempt to use it indiscriminately, we shall bring discredit upon it. If the dosage used is inadequate or if its administration is for too short a period of time, many patients will be deprived of benefit which would otherwise be theirs. The full scope of its usefulness has not yet been determined. Many clinical experiments are in progress. More and more reports are appearing in the world literature. I have no hesitancy in prophesying that we shall hear much more about the therapeutic value of vitamin B_1 in the next few years.

Large Diverticula of the Gastric Cardia*

By

GARNETT CHENEY, M.D.

and

ROBERT R. NEWELL, M.D.

SAN FRANCISCO, CALIFORNIA

TRUE diverticula of the stomach are uncommon and although often symptomless may cause confusion with other types of lesion. Larimore and Graham (1) in a series of 3,446 gastro-intestinal X-ray examinations observed 105 diverticula, only three of which were in the stomach. We encountered only two instances of gastric diverticula in 11,828 examinations done at Stanford University Hospital over a twelve year period. Our two other cases were seen at other hospitals. The Mayo Clinic reports fourteen cases proven anatomically (2), six of which were at the cardia on the posterior wall. They had in all twenty-five cases diagnosed by roentgen ray (2 and 3), only two of which were proven, and four of which

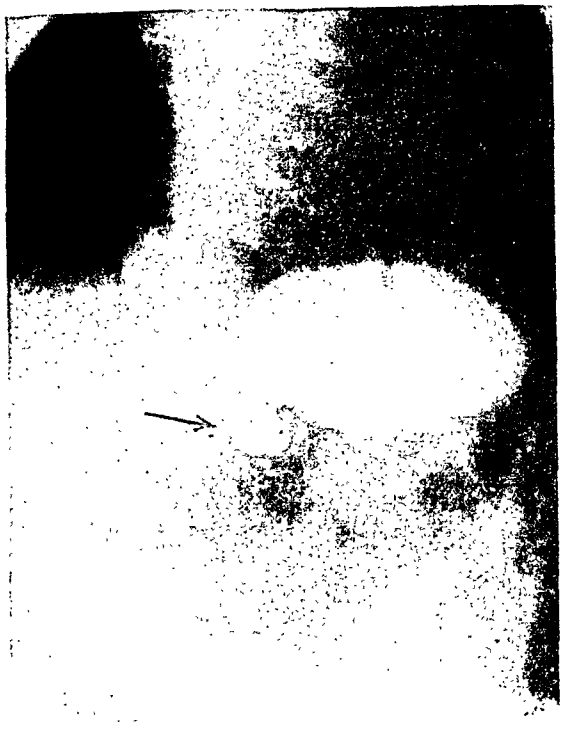

Fig. 1: Case 1. Diverticulum of the stomach at the cardia. Proved by operation.

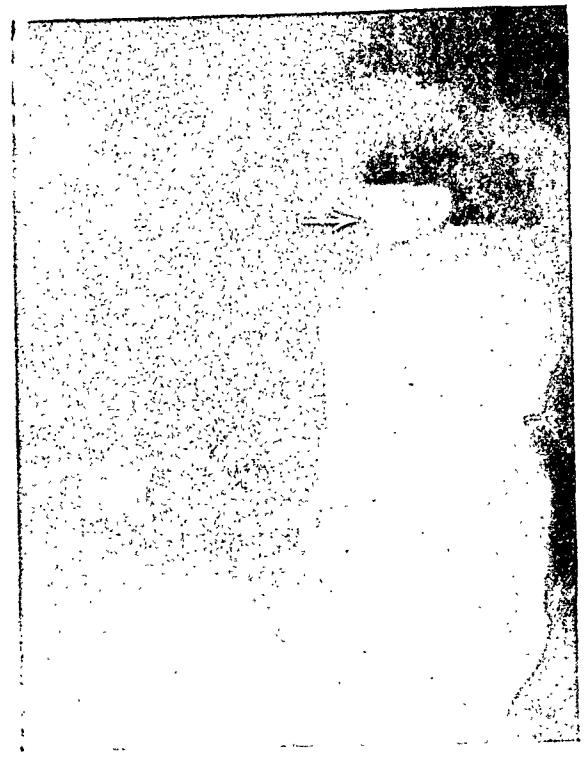

Fig. 3. Case 2. Diverticulum of the stomach at the cardia. This did not fill from the esophagus but only by reflux from the stomach. It was still full of barium after twenty-four hours.

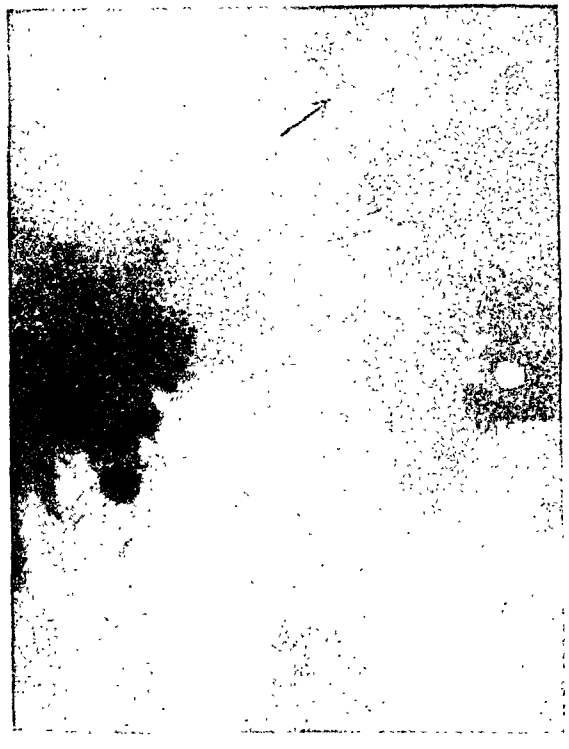

Fig. 2. Case 1. Residue in gastric diverticulum twenty-four hours after barium meal.

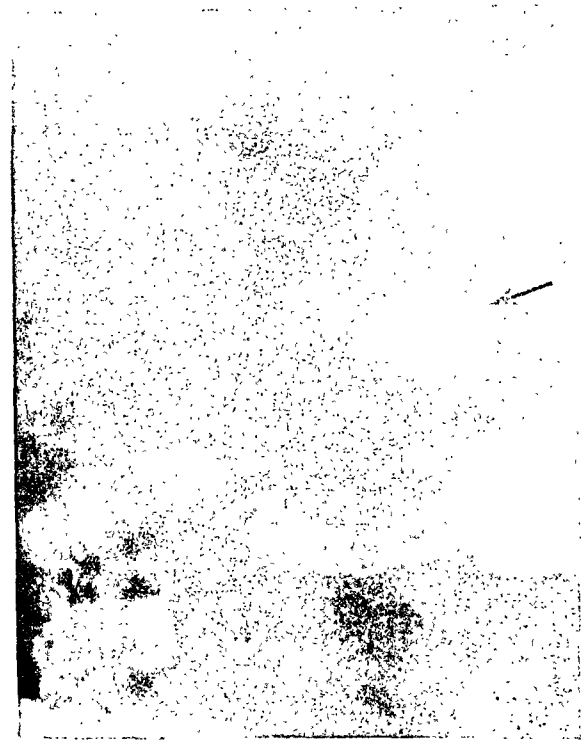

Fig. 4. Case 3. Diverticulum of the stomach at the cardia. It measured three and one-half centimeters in diameter.

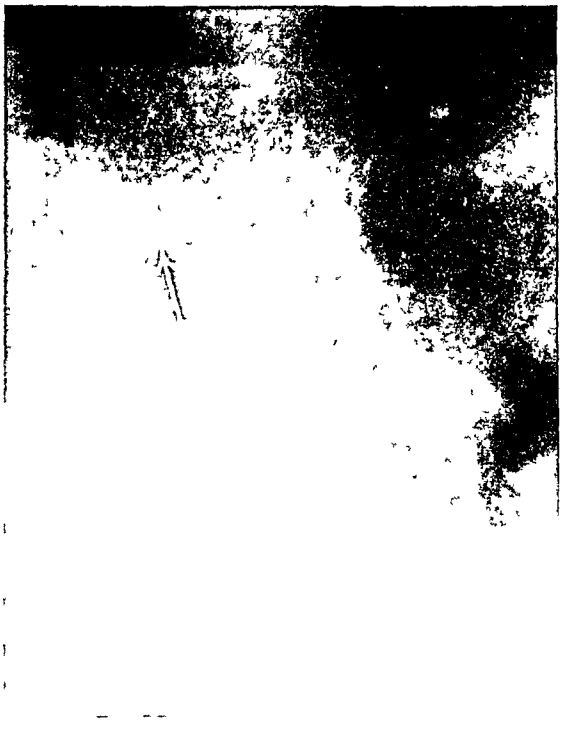

Fig. 5 Case 3. The diverticulum was still full four hours later. Attempts to hasten its emptying by putting patient on right or left side or even head down always were ineffective.

were shown actually to be something else. In 64% of their cases there were no symptoms attributable to the diverticula, and even in the other cases the origin of the patients' complaints was uncertain. Neoplasms and ulcers were found in or near the pouches in several instances, but only one case was complicated by hemorrhage. Most recently Martin (4) has collected data on 103 published cases of uncomplicated pulsion diverticula of the stomach, including five from the post mortem records of the Johns Hopkins Hospital. He was unable to find the record of a single case diagnosed, ante mortem, either clinically or by X-ray.

True primary diverticula are thought to be congenital in origin and are distinct pathologically from those due to extrinsic or intrinsic disease of the stomach wall. There are no characteristic symptoms upon which to base a diagnosis, consequently the X-ray examination is all-important, but it will not always reveal whether the diverticulum is a true or a false one.

We are reporting four examples of this rare gastric lesion. One patient was operated upon. The large size of the diverticula in the others makes the X-ray diagnosis reasonably certain.

Case 1 Miss F. H., age 20, complained of indefinitely-localized pain in the abdomen at times without relation to meals. Films of the gall bladder showed a calcified stone a centimeter in diameter. Barium meal revealed a pouch more than two centimeters in diameter on the lesser curvature of the stomach just below the cardia. This retained barium for at least twenty-four hours. Dr. Stillman removed the gall stone in January, 1926, but this operation failed to stop the pain. In August, 1926, he operated again and invaginated the diverticulum. He found no evidence of inflammation there. No biopsy was done to discover what coats were present in the wall of the pouch. The patient's pain was relieved.

Case 2. Mrs. E. V. C., a 62 year old widow entered the hospital December 2, 1929, complaining of indigestion. She had had irregular burning pains in the stomach unrelated to meals on and off for twenty years. Two years previously an X-ray diagnosis of duodenal ulcer was made and she has been on a modified Sippy regime since that time, but only with partial relief. *Physical examination* revealed moderate epigastric tenderness. The blood count was normal. The stool was negative for occult blood. The blood Wassermann was negative. Fractional gastric analysis after a histamine "test meal" showed small volumes of gastric secretion but a free acidity of 100° and a total acidity of 110°. A diverticulum of the stomach demonstrated by X-ray examination is illustrated in Fig. 3. No evidence of a duodenal ulcer was found. She was dismissed with a clinical diagnosis of psychoneurosis. She was known to be alive and well five and one-half years later.

Case 3. Mr. P. O., a 71 year old longshoreman, was in the hospital in 1929 for osteomyelitis of the big toe. In 1931 he entered again, his toe still sore, and complaining of occasional gastric distress and retching during the past month. He had had no severe pain and had not vomited. He used alcohol excessively at times.

In June, 1934, he entered again and has been under continuous observation since. During this time he has had four severe, acute abdominal attacks consisting of dull aching pains, burning, vomiting and abdominal distension. The abdomen is diffusely sore at the time of these episodes, but there is no localized tenderness. Each attack has followed a bout of heavy drinking. Blood has not been found in vomitus or stools, grossly or by chemical

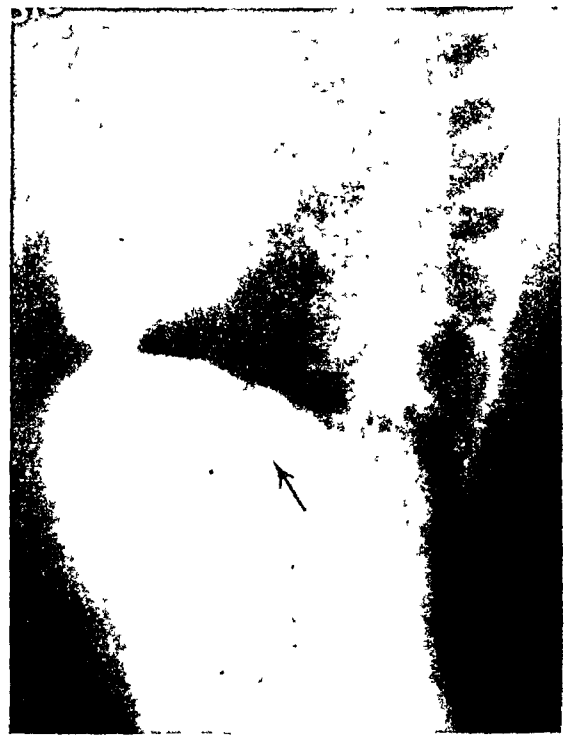

Fig. 6. Case 4. Diverticulum of the stomach near the cardia. (Lateral exposure).

Fig. 7. Case 4. Twenty-four hours after the barium meal, the gastric diverticulum is filled half with barium and half with air. (Antero-posterior exposure).

test. No leukocytosis was ever found. Gastric analysis after the injection of half a milligram of histamine, removing five samples at ten minute intervals, revealed a free HCl reaching 90° and a total acidity of 95°. All specimens contained excessive amounts of bile. A description of the gastric diverticulum found by X-ray examination accompanies Figs. 4 and 5. The patient is on a modified Sippy diet as he feels he has less indigestion than when following a regular diet. His substernal burning sensations are relieved by Sippy powders.

Case 4. Mrs. M. L. W., a 38 year old stenographer complained of lack of energy. She had two spontaneous miscarriages. Her appendix was removed in 1921 and a cystic ovary and one tube in 1923. Tonsillectomy was done in 1925 and curettage in 1928 and 1929. She had never been well since. She was weak, dizzy, faint and short of breath, and unable to do routine housework. She had no gastro-intestinal symptoms except moderate constipation.

On *physical examination* she appeared delicate. Both pupils showed congenital inferior coloboma. The blood pressure was 102/75. Old operative scars were present in the lower abdominal wall. Blood, urine and stool examinations were normal. Gastric analysis after an alcohol test meal revealed 6° of free HCl. The basal metabolism varied between plus five and minus eighteen. X-ray of the chest was negative. X-ray of the teeth revealed one area of periapical infection. The roentgen appearance of her gastric diverticulum is shown in Figs. 6 and 7.

Volvulus of an Inverted Intrathoracic Stomach Complicating Diaphragmatic Hernia---Case Report

By

ARTHUR BOWEN, M.D.
LOS ANGELES, CALIFORNIA

THE history, symptoms, clinical and X-ray findings in this interesting case present in brief, a summary of the problems in differential diagnosis and complications of diaphragmatic hernia.

At one time or another, all of the abdominal viscera, except organs situated in the pelvis, have been found above the diaphragm in a hernia. (Richardson) (1). Of surgical importance are the stomach and colon, especially the transverse portion and the small intestines.

The first case of complete volvulus of the stomach was described by Berti in 1866. Berg in 1895 was the first to operate for gastric volvulus.

INCIDENCE OF VOLVULUS OF THE STOMACH

Payer (2) could find only 22 cases of volvulus of the stomach reported in the literature from 1866-1909 and quotes 500 cases of diaphragmatic hernia with 12 cases of gastric volvulus. Lahren (1927) summarized the literature reporting that there were then 40 known cases of gastric volvulus. Sutter (3) analyzed the 58 cases in the literature up to 1929. Sutter, however, excluded all cases which were due to diaphragmatic hernia. Deaver and Ashurst (4) (1921) state that volvulus of the stomach appears to have been observed in at least 35 cases, and that there are on record at least 22 operations for gastric volvulus. Anagnostidis (5) (1935) found reports of 116 cases of volvulus of the stomach.

Knaggs (6) (1904) reported 3 cases of volvulus of the stomach, complicating diaphragmatic hernia and remarks that strangulation affected that part of the stomach which had not entered the hernia; while the hernia contents themselves were quite normal. He explains that as due to interference with the circulation through the coronary vessels.

Submitted November 10, 1936.

Fig. 1. Real hydropneumothorax. Note: Heart not displaced, collapsed lung compressed against mediastinum, no lung tissue visible through gas-filled area.

All or only part of the stomach may be involved. The torsion may be: (1) around the axis from the pyloris to the cardia—the so-called organo-axial or pyloro-cardiac volvulus; (2) around the axis from the greater to the lesser curvature, the so-called mesenterico-axial volvulus, or (3) of a mixed type. In the series of 116 cases studied by Anagnostidis (5), the volvulus was described in detail in 108 and in 57 (52.7%) it was of the organo-axial type; in 45 (41.6%) of the mesenterico-axial type, and in 6 (5.5%) it was of the mixed type. In 43.9% of the 116 cases recorded in the literature the condition was described as idiopathic.

CASE HISTORY

H F, male, age 40, was seen for the first time on October 10, 1934, 1 A. M., for relief of what the patient termed as a "heart attack." The evening of the 10th, after partaking of a heavy meal, the patient began to complain of pain in the left chest, dyspnea and vomiting. On examination, a moderately obese middle-aged man appearing acutely ill with dyspnea, cyanosis, weak rapid pulse, profuse cold perspiration, and repeated projectile vomiting of foul brown fluid. The chest was barrel-shaped. No apical impulse was palpable in the left precordia. There was tympany in the left upper chest, with flatness in the left lower. There was dullness to the right of the sternum. Apex beat palpable 1 inch within right nipple line. Pulse 120, respiration 24, blood pressure 90/40. Distant breath sounds were heard in the left apex.

The dyspnea and cyanosis directed one's attention to the chest. The shock and vomiting to the abdomen. The abdomen was soft, flat, no masses or tenderness, no peristaltic waves. The displacement of the heart and percussion and auscultatory changes pointed to chest pathology.

On further questioning the following information was elicited: That he had recurrent attacks past 8 years. Last attack one month ago with pain in chest, dyspnea, and vomiting. Seen by physician who administered 2 hypodermics—patient felt better next day. Inquiring if any X-ray had been taken, the wife stated that he had been studied in a New York hospital, found to have an unusual condition—and that she had hidden the plates in her trunk. The X-rays were found and revealed a stomach within the thoracic cavity, hanging in an inverted position, also the presence of the large intestine in the thorax.

The vomiting, tympany of left chest and the presence of large intestines in the thorax made one suspicious of possible angulation or kinking of the herniated large gut. *But*—the absence of any abdominal distension was opposed to any obstruction or incarceration of the large bowel. The following morning patient felt somewhat better. That afternoon he started spilling over more brownish fluid. He was seen and found to have a fuller stronger pulse, dyspnea and cyanosis still present but not as marked, no pain. Pulse 100, temperature 97, respiration 20. The abdomen remained soft. The patient was reluctant to enter the hospital for observation since his previous attacks, he argued, were relieved without hospitalization. After persuasion he was admitted to the Cedars of Lebanon Hospital the evening of the 10th with a diagnosis of a partial volvulus of the stomach complicating diaphragmatic hernia.

On admission to the hospital, his temperature was 99.6, pulse 120, respiration 20. The following procedures were instituted: Levine tube was passed intranasally for continuous drainage of the stomach. 60 c.c. of brownish fluid were obtained. An intravenous glucose and saline 1000 c.c. was slowly given so as not to embarrass the heart. Rectal tube to relieve any gas in the large gut. Morphine and atrophine for pain. That evening patient was much more comfortable. Small amount of drainage was passing through Levine tube. Had a fairly good night. The following morning, 24 hours after admission, temperature rose to 101, pulse 115, respiration 28. Cyanosis was more marked, breathing more labored. Several hundred c.c. of gastric fluid drained through tube during the night. Changing the position of the patient increased the amount of fluid that could be withdrawn with the syringe attached to the Levine tube.

If one saw the patient propped up in bed with cyanosis of lips, face, fingernails, with a thready rapid pulse, marked dyspnea, and temperature rising to 103 one was sure it was pneumonia. The chest findings would confirm any number of diagnosis. The signs in the chest could not be interpreted in terms of either *normal* or *pathological thoracic* findings because the patient had abdominal viscera in the thoracic cavity. The patient was transferred on his bed to the X-ray room to observe what was happening within the chest. X-ray showed the Levine tube

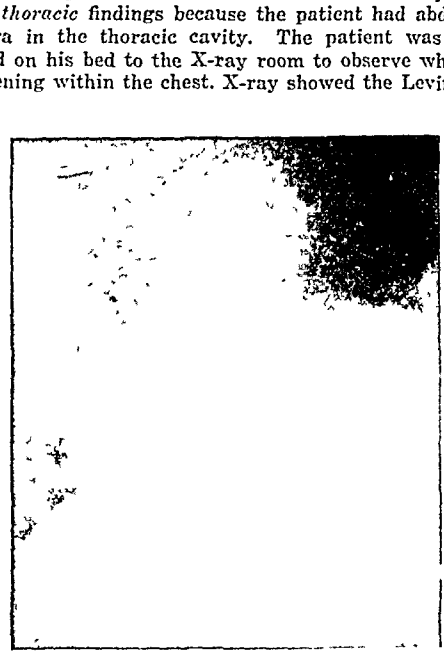

Fig. 2. X-ray of patient March 2, 1927. False hydropneumothorax. Note: Heart displaced to right, lung not collapsed, but surrounds gas-filled area, which occupies a central position. Some lung tissue can be seen through the gas. Stomach full.

Fig. 3. Same as Fig. 2 on fasting stomach. Note: No fluid level, large gas bubble.

in the esophagus, stomach greatly dilated, occupying most of the thoracic cavity (Fig. 8). Displacement of the heart to the extreme right. While the patient was being propped up for X-ray, the patient shook himself and a considerable flow of brownish fluid was noted escaping from the tube. Shaking the patient from side to side gave one the impression of shaking a half empty bottle of water. The fluid was sent to the laboratory for examination for blood and bile. If there was fluid trapped in the stomach, was it coming from obstruction below or at the stomach. IF bile was positive—the obstruction was beyond the duodenum. IF bile was absent—the obstruction was above the duodenum. The laboratory report was repeatedly negative for bile, but strongly positive for occult blood. White and differential 27,000, Polymorphonuclear count 80. Blood Chemistry: Chlorides 421, CO_2 72. Urine—occasional hyaline cast.

E. K. G. Reading: Auricular and Ventricular rate of 135 with normal rhythm; and very advanced degree of myocardial degeneration that is probably associated with coronary thrombosis. Simple tachycardia.

Upon reviewing the X-ray, laboratory and clinical findings, I ventured a diagnosis of volvulus of the stomach. My reasons for this diagnosis were: (1) Patient had an inverted stomach within the thorax for many years as seen on X-ray taken in 1927. The fluid level in the stomach persisted despite drainage via the Levine tube—nor did the gastric contents empty via the pylorus—suggesting an obstruction at both the pyloric and cardiac ends—Volvulus would produce just such a condition. (3) No abdominal distention—which meant no obstruction of the thoracic portion of the colon. (4) Absent bile in the gastric drainage indicating that the obstruction was not below the duodenum, else bile would have been backed up into the stomach.

Upon return from the X-ray room a Connell continuous suction apparatus was connected, with the hope that if the obstruction was not complete, the stomach could be emptied by continuous suction. More intravenous fluids were given. Oxygen tent to relieve dyspnea and cyanosis. Patient was urged to shift positions—to aid gastric drainage.

The question of surgery was approached but rejected by the family because he had always recovered from the previous attacks. Because of the serious condition of the patient a palliative thoracic procedure to empty the stomach with a trocar followed by suture and reduction of the volvulus was considered, with a more radical repair of the hernia proper at a later date. That evening his pulse rose to 125 growing weaker. Temperature 103, respiration 30. Stimulation was given. During the night condition grew progressively worse, and the patient died the following A. M.—38 hours after admission. Permission for autopsy was obtained and findings are noted below.

AUTOPSY REPORT

Very well developed, muscular, robust male, said to be 40 years of age and having the appearance of stated age.

Abdomen. On opening the abdomen there was found an old hernial orifice through the crura of the diaphragm. The sternum was removed in order to expose this hernia. The stomach, transverse colon and greater omentum were found to be in the left thoracic cavity, displacing the left lung towards the spine and apex of the chest. The right lung was compressed and the heart shoved over to the right chest, so that the left border of the heart was to the right of the right border of the sternum. The stomach was twisted on itself and pulled up into the chest so that the greatest constriction was just at the pylorus and the pylorus was on a level more cephalic than the cardia. The stomach was also twisted on itself so that the greater curvature, in the main, follows the left border of the sternum and the posterior wall of the stomach was plastered to the left chest wall. The greater omentum occupied the anterior portion o fthe chest and was adherent to the sternum and ribs. A large portion of the transverse colon was in the left chest and it lay posterior to the stomach. Apparently the hernial orifice was anterior to the esophageal opening in the diaphragm and separated by a fibrous septum from the cardia.

Stomach ligated and removed. It contains in excess of four quarts of fluid—this fluid was slightly blood stained. The rotation of the stomach was such as to cause tortion at the cardia acting as a stricture. The pylorus was incarcerated through the hernial orifice and the adhesions were rather dense at the orifice in the diaphragm. On removing the stomach, it was found to be greatly distended and there were mucous erosions, possibly due to stretching of the mucosa. There were no ulcerations or necrotic areas in either the stomach or transverse colon.

Thorax. Left lung shows complete atelectasis. Right lung was compressed, but shows no pneumonic areas.

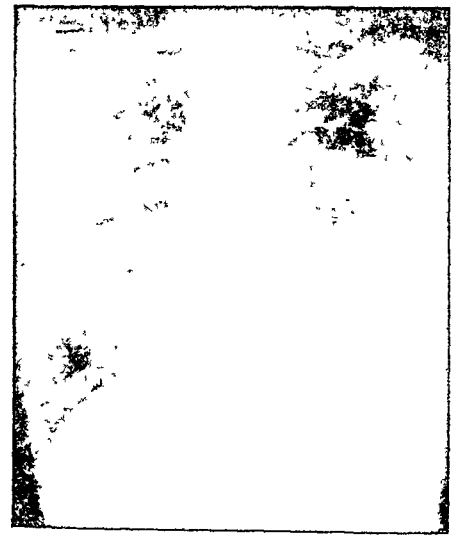

Fig. 4. Same as Fig. 3 after introduction of stomach tube and aspiration of fasting contents. Note: Diminution of gas bubble and expansion of lung.

Fig. 5. Stomach full. Oblique view. Duodenal bulb above cardia. Stomach completely inverted.

Heart normal in size. There were pericardial adhesions at various points.

Remaining abdominal viscera not remarkable.

PAST HISTORY

I am indebted to Dr. Zachary Sagal (7) for the following interesting details of this patient's past history. The patient was born in Crimea, Russia, and has always enjoyed good health. Upon careful questioning, however, it was brought out that while he had no difficulty in playing games with the boys, he could never keep up with them in climbing mountains or in any other strenuous physical exercises. In 1914 he was drafted into the Russian Army and was sent to the front. In January, 1915, while shooting in lying position on his abdomen on level ground, he was wounded in the lower back by a piece of shrapnel. He did not become unconscious, although he lost considerable blood. He was in a hospital for several months until the wound was healed. There was no paralysis or difficulty with rectal or vesical function. During his hospital stay he was X-rayed to determine whether any piece of shrapnel was remaining in his back, but none was found. He observed, however, that the doctors X-raying him showed great surprise and displayed unusual interest, demonstrating him to other staff members. He could not understand their conversations, but knows there was no fracture. After discharge from the hospital, he remained a war prisoner for three years and escaped back to Russia in 1918. Upon return to Russia he was confined to prison as a political suspect for a long period of time, and then managed to escape to Constantinople where he lived for over a year, and in 1922 he emigrated to America. In spite of all his hardships, he was always in perfect physical condition.

In September, 1925, after a heavy meal, he suddenly developed an attack of marked oppression in the chest and was only relieved after a hypodermic injection of a narcotic and after copious vomiting. A similar attack occurred in April, 1926. It was associated with nausea, severe pain in the back, profuse perspiration and headache. Physical examination revealed distant breath sounds in the left apex with few rales. There were elicited all the classical signs of hydropneumothorax of the left chest. He was again relieved by the administration of a narcotic and after vomiting. A medical consultant was called in and he also found signs of fluid and gas in the left chest and confirmed the diagnosis of hydropneumothorax. The question of etiology was not clear, whether it was due to pulmonary tuberculosis or was the result of the injury received in the war. He was referred to one of the largest hospitals in New York for observation and treatment. The following is the communication sent by the hospital in answer to Dr. Sagal's inquiry:

"Date of admission to hospital—April 29, 1926.

Date of discharge—May 11, 1926.

Diagnosis: Hydropneumothorax; pulmonary tuberculosis.

Last known condition improved.

X-ray report April 30, 1926: Examination of the chest shows a collection of fluid in the left chest extending up to the level of the fourth rib anteriorly. Above this there is a pneumothorax extending up to about the second rib anteriorly. Surmounting this the collapsed lung is seen, which shows no definite abnormality except perhaps some fibrosis. The heart and mediastinum are displaced to the right side.

Final note: Patient with a negative history who enters with complaint of sudden sharp pain in the chest one month before admission. On physical examination there is evidence of hydropneumothorax in the left chest which is confirmed on X-ray examination. Also some fibrosis seen at left apex. Sputum repeatedly negative. Repeated aspiration was unsuccessful."

He left the hospital against advice, refusing to submit to further paracentesis. The next attack occurred January 30, 1927, and was even more severe than the previous attacks. His pulse was weak and rapid—rate of 130. He was relieved by vomiting of large quantities of recently ingested food, and after an enema.

He was referred to Dr. Zachary Sagal on March 22, 1927. His findings were: "Physical examination was essentially negative except for the chest findings. He looked well-nourished, weighing 193 pounds, height 5' 11". Had good color but seemed to be somewhat short of breath. The apex of the heart was located one inch within the right nipple line and is diffuse. Percussion of the right side disclosed an area of relative dullness extending to the right nipple. The percussion of the left side showed

Fig. 6. Five hours after meal. Small residue in stomach. Splenic flexure of colon above and lateral to stomach. Cecum in right iliac fossa.

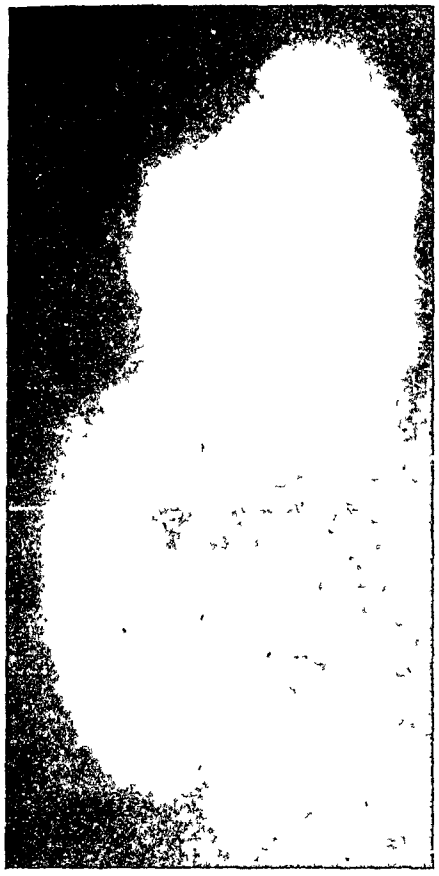

Fig. 7. Barium enema. Splenic flexure almost reaches the level of the left clavicle.

tympany in the upper half anteriorly as high as the clavicle. There is dullness over the left lower chest."

"X-ray examination of the chest shows a condition which very closely simulates hydropneumothorax (Fig. 2). However, there is no evidence of compression of the left lung. On respiration there is paradoxical movement of the upper level of the gas filled area. On close examination one can see some lung tissue through the gas. Re-examination after aspiration of the stomach reveals a marked change in the picture (Fig 4). The gas area is considerably lower, the fluid having disappeared and the lung in the left chest becomes more prominent. This occurs only when the stomach is emptied by means of a tube, but the fasting stomach (Fig. 3) shows a very large gas bubble. The left diaphragm cannot be seen, and the left base is quite dense."

"Upon administration of an opaque meal (Fig. 5), the stomach is seen to be filling in water-trap fashion, is completely inverted, the cardia being just above the level of the diaphragm, the lower pole occupying the highest portion in the chest. The pylorus and first portion of the duodenum lie mesial and behind the cardia, crossing it on entering the abdominal cavity. Further study reveals that part of the colon is also in the thoracic cavity. It required two large films to take a roentgram of a barium enema, as the colon extends from the right iliac fossa to the left clavicle (Fig. 7). There was no disturbance in the motility of the stomach or intestine. The left diaphragm could at no time be definitely visualized and is entirely absent or deficient to such an extent as not to be demonstrable."

The patient had no trouble until January, 1929, when another severe attack occurred. He was readily relieved after evacuation of the stomach. Another attack occurred in August, 1931, and also was relieved.

Comment: There is nothing in the history to suggest that the condition was due to trauma. The shrapnel wound was sustained when the patient lay flat on his abdomen, and he was hit from above. Rupture of the diaphragm usually occurs when a severe blow is dealt on the abdomen, or when the abdomen is severely compressed, neither of these conditions having occurred. Nor are there any symptoms indicating respiratory or circulatory embarrassment, as would be the case in sudden extensive herniation of the abdominal viscera into the thorax. He had no difficulty in his adult life, and withstood the rigors of army regime. Judging from the description supplied by the patient and the attending physicians, the attacks were probably due to recurring volvulus of the stomach which untwisted itself under the relaxing effect of narcotics or by change of position by the patient. One can readily visualize how the stomach in its inverted position when overloaded, may sag and by its own weight close off both the cardiac and pyloric orifices.

Dr. Sagal (7) reported this case in the American Journal of Roentgenology and Radium Therapy as a case of "absence of left diaphragm with inverted thoracic stomach." The reported case is not the only one in which the presence of the stomach in the thorax was mistaken for tuberculosis and hydropneumothorax. Truesdale (8) in 1921 operated on a child of five who was run over by an automobile nine months previously. The child had spells of dyspnea, cyanosis, and distress after eating. He was examined by many physicians who concluded the child had tuberculosis of the lungs with cavity formation. The left thoracic cavity was found to contain the stomach, small intestines, colon, left lobe of the liver and spleen.

O'Dwyer (9) in 1889 operated on a child of three who had a congenital diaphragmatic hernia. The case had been diagnosed as purulent pleurisy. Thoracotomy was done and a diaphragmatic hernia containing small intestines was found.

Giustinian and Antonelli (10) (1931) report a case of an infant twenty-two months old who was admitted with a diagnosis of bronchitis and pleural congestion with serofibrinous pleurisy. A double pleural puncture at the seventh and eighth intercostal spaces yielded a few drops of serous fluid. X-ray seven days after admission did not clear up the diagnosis. Autopsy revealed the greater part

Fig. 8. X-ray taken October 10, 1935, shows Levine tube in esophagus, stomach greatly dilated, occupying most of thoracic cavity. Marked displacement of heart.

of the right hemithorax occupied by the small intestines, cecum, appendix, ascending colon and middle part of the transverse colon.

Struppler's (11) case had nineteen exploratory punctures before the correct diagnosis was made. Truesdale (8) cites a case in which milk was aspirated from the chest by exploratory puncture. Lebon (12) reports two cases of false pneumothorax, one in a soldier who had the stomach punctured twice by parancentesis thoracis. Likewise, Stivelman (13), doubting the diagnosis of pneumothorax in a tuberculous patient, administered a barium meal and found the case to be one of eventration.

The opaque meal and roentgenoscopy should never be omitted after a careful analysis of the history and physical findings make one doubtful of the presence of a *hydropneumothorax.*

Ball (14) (1935) has suggested having the patient swallow "Seidlitz Powder" to generate gas in the stomach for contrast in fluoroscopic and X-ray examination.

SUMMARY

A case of diaphragmatic hernia has been presented with a history of chronic recurrent attacks of partial obstruction of an inverted intra-thoracic stomach in whom clinical and X-ray findings led to a mistaken diagnosis and treatment for tuberculosis and hydropneumothorax with repeated paracentesis, and the final development of acute complications due to volvulus of the stomach with acute dilation sufficient so to embarrass the heart and lungs as to cause death, with autopsy findings to substantiate clinical and X-ray findings.

CONCLUSIONS

1. The symptoms and physical signs of diaphragmatic hernia are varied and complex; clinical diagnosis is difficult without X-ray examination.
2. Diaphragmatic hernia is frequently mistaken for disease of the gall bladder, stomach, heart and lungs.
3. Obscure chest and abdominal symptoms demand X-ray of the gastro-intestinal tract as well as of the chest to rule out hernia.
4. Respiratory difficulty and recurrent obstructive symptoms in infants and children should lead to a suspicion of diaphragmatic hernia.
5. Diaphragmatic hernia should be suspected in crushing injuries of the chest and abdomen.
6. The mortality of those operated on before obstruction has occurred has in recent years not been higher than that of other abdominal operations.

The author wishes to express his indebtedness to Dr. Zachary Sagal for the details of the patient's past history and for his kindness in forwarding me negatives of the films used as illustrations in this article.

SECTION V—*Therapeutics*

Chaulmoogra Oil in the Treatment of Lymphopathia Venerea*

By

GEORGE M. LANDROCK, M.D.
PHILADELPHIA, PENNSYLVANIA

LYMPHOPATHIA venerea continues to be the greatest etiological factor in the cases of *rectal stricture* seen in this clinic. Dr. Collier F. Martin (1) in 1935 ably explained the reason for the greater incidence in the female negro in this clinic.

Lymphopathia venerea is a virus infection transmitted in most instances through venereal exposure. The site of the initial lesion in the female is commonly either the fourchette, the posterior wall of the vagina, or the posterior lip of the cervix. From these foci the infection spreads posteriorly to the perirectal lymph nodes and lymphatic network. The process goes on from lymphangitis with round cell infiltration to the formation of miliary abscesses in the rectal wall. The tissues react with the loss of some of the mucous membrane as some of the small abscesses perforate into the lumen of the rectum. Fibrosis develops around these miliary abscesses and sinuses. The result is either a band-like or tubular stricture of the rectum. The large majority of patients give a positive reaction to the Frei test.

Most of these unfortunate patients are not seen until the process is well advanced, presenting symptoms of constipation, blood and pus in the rectal discharge. Eventually most of these patients with stricture require colostomy.

Stannus (2) states: "In no known virus disease is there any specific chemo-therapeutic treatment at present available and lymphogranuloma inguinale appears to be no exception to this general rule." Never-

Submitted October 7, 1936.

theless, when one sees a disease which eventually kills the patient, it is quite natural to try experimental therapy with agents which have been of value in other diseases with similar pathology. With this consideration in mind, Doctors Collier F. Martin, Robert Hunter and Harry Z. Hibshman suggested the therapeutic use of chaulmoogra oil in patients with lymphopathia venerea. They recognized a parallelism in some of the pathological characteristics of this disease and leprosy such as granulomatous changes, hypertrophies of the skin, abscesses and fistulae. A study of the clinical changes, if any, following the use of chaulmoogra oil in the course of treatment of these patients seemed desirable.

A series of patients was selected for this study. Each gave positive Frei reactions and suffered from some type of anorectal pathology. The patients were given intramuscular injections of chaulmoogra oil, from one to two cubic centimeters per dose, once or twice a week for from four to six weeks. Clinical changes in the appearance of the local lesions and in the general well being of the patients were noted during the course of treatments and six weeks after discontinuance of the treatment.

Case 1. L. J. The patient a negro female of twenty years, single, was first seen in the clinic in October, 1935, complaining of constipation, pain during and after bowel movements, and occasional appearances of blood at time of stool. She had a posterior anal ulcer, moderate congestion of the rectal mucous membrane, and beginning thickening of the posterior wall of the rectum above the anorectal line. She gave a positive Frei reaction and negative reactions to the Wassermann, Kolmer and Eagle tests. The anal ulcer and infected crypt above the ulcer were excised. Although the patient complained of less pain following operation, the wound healed very slowly. Excessive granulation tissue recurred over a period of three months in spite of its removal by cutting and the application of strong solutions of silver nitrate. From January 25, 1936, to March 14, 1936, she was given eight intramuscular injections of chaulmoogra oil. Her general condition at the time of the last injection seemed better. She stated that she felt stronger and had more energy. The cutaneous portion of the operative wound had healed from without inward to a point midway between the anal margin and the anorectal line. Proctoscopic examination revealed an ulcer posteriorly with indurated margins in the upper part of the anal canal. For a distance of four to five centimeters above the anorectal line was seen a moderately severe ulcerative proctitis with patches of fibrinous exudate. There was no improvement noted when seen six weeks later. The patient was aware of a rectal discharge of blood, pus and mucus. The proctoscopic examination gave the same picture of ulcerative proctitis with beginning fibrosis in the posterior wall, a forerunner of rectal stricture.

Case 2. R. D. The patient, a negro female, twenty-nine years, single, was first seen in November, 1934, complaining of difficulty with her stools and of the escape of gas from an opening in the perineum between the anus and the vagina. She had an anterior anorectal fistula, a posterior anal ulcer, and an annular rectal stricture about six centimeters above the anal margin. The Frei reaction was positive and the Wassermann test negative. The ulcer and fistula were excised in September, 1935. The posterior wound healed in about six weeks, but the anterior wound did not heal. There was a return of the discharge in the anterior wound and the appearance of excessive granulation tissue was noted. On January 25, 1936, the rectum admitted a number 18 Hegar dilator with discomfort to the patient. She was given weekly doses of chaulmoogra oil, one cubic centimeter intramuscularly, for seven weeks. During the third week she complained of an attack of diarrhea. Since none of the other patients in this series complained of diarrhea, little significance was paid to this symptom. About the fourth week the skin wound had nearly closed and there was very little purulent discharge from the wound. However, during the sixth week the wound began to discharge more freely with breaking down of tissue. There was of course no improvement as far as the stricture itself was concerned. There was a moderate amount of ulceration of the mucous membrane in the region of the stricture. She was examined again six weeks later with no evidence of further improvement.

Case 3. R. M. The patient, a negro female, forty-nine years, widow, was first seen in this clinic in November, 1929, complaining of difficult bowel movements. She first noticed constipation when she was a resident of Texas at the age of twenty-one years. In 1910 she had a hemorrhoidectomy. In 1911 she had an anterior anorectal abscess, which was promptly excised. After removal of sutures, she noticed drainage from the vagina as well as from the rectum. At that time a diagnosis of rectal stricture was made, and the condition was treated by dilatation with sounds. Her condition has become progressively worse. Upon admission to this clinic, she was found to have an advanced tubular stricture of the rectum of extremely narrow calibre with discharge of blood and pus from the vagina and rectum. She was required to take saline laxatives to keep the stools liquid. She also had a rectovaginal fistula. She was advised to have a colostomy, and after some delay, her consent was obtained and the operation was performed in September, 1930. Her general health improved, but the fistula persisted. The fistula was excised later in 1930. A pathologist reported the excised tissue as being tuberculous. In 1931 she developed extensive hypertrophy of the vulvae. The left labium majorum was removed in October, 1931. She was more comfortable for a few months, but later ulceration of the cutaneous surfaces and of the mucous membranes involving both labia minora, clitoris, and rectum developed. A Frei test was done May 10, 1933, which gave a definitely positive reaction. A diagnosis was then made of lymphopathia venerea with rectal stricture, rectovaginal fistula, esthiomene, and cutaneous ulceration. Six operations were done in 1931 to remove painful ulcerative lesions. In November, 1935, she was in considerable pain, had become gradually weaker, and was very much depressed and discouraged. In December, 1935, the right labium majorum was removed, from which an antigen was prepared. She was given five or six intravenous injections of 1:1500 solution of hydrochloric acid during the latter part of December, 1935, and the early part of January. There was a marked improvement in her general condition and less discharge from the wound which had a healthier appearance. On January 25, 1936, injections of the hydrochloric acid were discontinued and chaulmoogra oil, one cubic centimeter intramuscularly, were given once a week. February seventh she complained of more pain in the wound and more purulent discharge. She was depressed and had lost weight. On April fourteenth the injections of hydrochloric acid solution were resumed. Six weeks later she stated that she felt better. There was no material improvement at that time in the condition of the ulcerative lesions. There was slightly less purulent discharge.

Case 4. H. L. The patient, a white male, fifty-five years, single, a trolley conductor, was first seen in our clinic in November, 1935, complaining of itching and moisture around the anus for the past six or seven years. He had been operated upon fifteen years ago for rectal fistula in a Philadelphia hospital. He stated that he was well for several years after the operation, although the wound healed slowly.

Examination revealed a short anorectal sinus. No external fistulous opening was demonstrated at the time of

examination. He had, however, a posterior anal ulcer and inflammation of the over-lying crypt which were removed by endotherm December 30, 1935. Although he gave no definite history of a venereal bubo, he had had five different herniorrhaphies. On January 2, 1936, Frei tests were done with positive reaction. The wound healed slowly. There was no evidence of rectal stricture. Beginning January 23, 1936, he was given weekly injections of chaulmoogra oil intramuscularly. February twenty-ninth it had apparently healed. April fourteenth he was re-examined and it was found that the wound had broken down with a discharge of pus.

Case 5. A. T. The patient, a negro female, married, thirty-one years, factory worker, had been admitted at this clinic in 1934. At that time she had a tubular stricture and gave a positive Frei reaction (July 8, 1934). Her husband was tested about three weeks later and likewise gave a positive reaction to the Frei test. The stricture had been treated by the carbon dioxide method with favorable results for several months as far as the calibre of the stricture was concerned. In 1932 she had an anorectal abscess.

She returned to this clinic in January of this year complaining of extreme weakness, palpitation, tachycardia, was anemic, and was given an iron tonic. The rectal examination revealed a tubular stricture of the rectum beginning six centimeters from the anal margin. There was elephantiasis of the right labium minorum. February tenth treatment with chaulmoogra oil was begun. She received weekly injections for a period of five weeks. There was an increase in the hemoglobin content. There was no improvement as far as the ulceration in the mucous membrane of the rectum was concerned. The stricture was relieved by dilatation with sounds.

Case 6. L. V. The patient, a young negro woman, twenty-three years, was first seen in January, 1936. She was a native of Savannah, Georgia. At the age of thirteen she began to have illicit sexual relations and became pregnant, giving birth to a child when fourteen and one-half years old. She married in 1931 and has had no further pregnancies nor miscarriages. She stated that she had "piles," about that time, but received no treatment. In 1933 she began to complain of constipation which became increasingly marked. She had ribbon stools, and required the use of saline laxatives to permit defecation. She noticed a discharge of blood and pus accompanying her stools. During the past year she has noticed a purulent discharge from the "external piles."

On inquiry her husband admits having had a sore, the size of a large pea, on the dorsum of the shaft of the penis. He was given a Wassermann test, which was 4 plus. He had enlarged lymph nodes in the left groin. He had phimosis and was circumsized and received a course of twelve injections of arsphenamine. Examination, when seen on March 20, 1936, revealed no evidence of buboes, except some palpable inguinal nodes. He was given a Frei test with several strains of antigen. He gave a positive reaction. His Wassermann reaction was still positive and he was advised to continue his antiluetic treatment.

The wife (L. V.) was found to have an advanced rectal stricture with three hypertrophied and fistulous anal skin tags, which the patient mistook for "piles." She was given a Frei test with several strains of antigen and gave a strong reaction. She was given six intramuscular injections of chaulmoogra oil weekly and although there seemed to be less secretion for about two weeks, there was no improvement in the rectal pathology of stricture with proctitis and ulceration. The rectum will admit a number thirteen sound with some difficulty.

COMMENTS

Our problem was to determine whether or not any therapeutic benefit might follow the use of chaulmoogra oil in lymphopathia venerea which pathologically resembles leprosy. Chaulmoogra oil is a mixture of chaulmoogric, hydnocarpic, and palmitic acids. Sollman (3) attributes the beneficial action of chaulmoogra oil in the treatment of leprosy to the selective toxic effect on the acid-fast bacilli (B. Leprae). It is therefore superfluous to expect any such selective action of these acids on the virus of lymphopathia venerea.

The patients with lymphopathia venerea have shown no consistent improvement following injections of chaulmoogra oil. Some of the patients showed a response with an attempt to heal skin wounds following fistulectomy, but the result was not permanent. In many cases there was an increase in the amount of purulent discharge from the fistulous tracts. Patients with rectal stricture showed no improvement. There was no improvement in the condition of the mucous membranes involved. Our experience, therefore, with chaulmoogra oil is that it is of no value in the treatment of lymphopathia venerea.

Lymphogranuloma Inguinale: Rectal Stricture and Pre-Stricture*

By
MANUEL G. SPIESMAN, M.D., ROBERT C. LEVY, M.D.
and
DAVID M. BROTMAN, M.D.
CHICAGO, ILLINOIS

THIS *paper constitutes a three year clinical study* of 115 cases of Frei positive lymphogranuloma inguinale strictures in a total consecutive series of 138 rectal strictures observed by us in the Cook County Hospital Gastro-Intestinal-Rectal Clinic.

ETIOLOGY

Predisposing Causes. Age. Of the 115 Frei positive cases studied, the youngest patient was 22, the oldest 57. The most common age was from 25 to 35. There was no significant difference in age distribution between male and female sexes. The views of other observers that lymphogranuloma inguinale is contracted in the age of most sexual activity is also noted by us in this stricture series.

Race. One hundred and four (or 90%) of our patients were Negroes, 10 (10%) white, and 1 (1%) Mexican. Ninety-eight (95%) of the females were Negroes; 5 (5%) were white. Only 5 (42%) of the males were Negroes; 6 (50%) were white; 1 (8%) was Mexican.

There is a general agreement in this country that the rectal stricture phase of this malady is most common in the colored race, especially in the colored female. Rosser (1) advanced the theory that the prevalence of stricture in the Negro may be accounted for partly by the racial predisposition to develop massive inflammatory deposits, which tendency he named "fibroplastic diathesis." Rosser also believes that the Negro is particularly susceptible to venereal infection as the result of the social conditions under which he lives.

Sex. One hundred and three (or 89%) of our patients were females, 12 (11%) males. A somewhat similar sexual incidence of rectal stricture has been remarked by nearly all observers.

Venereal factor. None of our female patients were virgins, in fact most were quite loose sexually.

Exciting cause. Of the total of 138 rectal strictures studied, 115 were found to have a Frei positive test (2), and form the basis for this report. Of the remaining twenty-three strictures, six were found by biopsy to be rectal carcinomas, four were due to nonspecific ulcerative colitis, two were post-operative anal stenoses, and eleven were of undetermined etiology. Of the 115 Frei positive stricture cases, seventeen (15%) also had a positive Wassermann. Twenty-six (22%) had a positive complement fixation test for gonorrhoea. Eight (7%) had a positive Frei, a positive Wassermann and a positive gonorrhoeal complement fixation test. There was no evidence of tuberculosis clinically or on X-ray of any of our patients. Biopsies made from the stricture in patients selected at random from our group, in no case showed any evidence of either syphilis or tuberculosis. We did not test our patients for chancroidal infection with Dmelcos vaccine because of the difficulty in obtaining the vaccine in this country.

CLINICAL COURSE OF LYMPHOGRANULOMA INGUINALE

We wish to emphasize that this is a venereal disease caused by an ultramicroscopic filtrable virus, with a primary lesion appearing on the external genitalia and secondary spread by way of the lymph channels to the lymph glands draining the region. In the male, lymph drainage is, on the whole, to the inguinal glands, so that bubos are common. In the female, lymph drainage is preponderantly to the glands of Gerota surrounding the rectum, producing a periproctitis and an obliterating proctitis or stricture. Because the lymphatic channels are liable to a good deal of variation as to their distribution and because the location of the initial lesion is variable, several types of lymphogranuloma inguinale lesions may develop in the female. We have noted (A) a "pre-stricture" lymphogranulomatous proctitis; or (B) a stricture with or without other complications. Associated with definite rectal stricture there may be (C) "cock's-comb" anal skin tags; (D) perianal "watering pot" granuloma with sinuses and fistulae; or (E) elephantiasis of the vulva (esthiomene or genito-ano-rectal syndrome); (F) a chronic lymphogranulomatous parametritis or pelvic cellulitis may be present with or without a rectal stricture; (G) stenosis of not only the rectum but the entire colon. Finally any and all combinations of the above types may be noted in any one patient. Table I shows these listed in the order of frequency of their occurrence in our series.

In our entire series, none could recall the initial lesion. The incubation period could not be determ-

ined. Only 30 patients (26%) could recall an inguinal bubo. The duration of rectal complaints varied from 4 weeks to 19 years. It is our present impression that rectal strictures are slow to develop and may take years to reach the stage where they produce symptoms.

Pre-stricture. Since we were on the lookout for cases of lymphogranuloma inguinale with early rectal involvement, we had the good fortune to recognize 7 Frei positive early proctitis cases where stricture had not as yet developed. We have designated this type as the "pre-stricture" stage of rectal lymphogranuloma inguinale. (Since the completion of this paper, we have seen 7 additional cases of the "pre-stricture" stage). Some of these patients were symptom free, and the lesion was discovered accidentally. Others complained of bloody or purulent rectal discharge, pain on defecation or of constipation. In these patients, digital examination elicited a somewhat thickened, infiltrated, inelastic rectal wall which contained scattered granulomatous nodules of varying size, starting about 5 cm. above the anal verge and extending upward for a varying number of centimeters. Proctoscopic examination showed erosions and the above purple-red granulomatous nodules which bled easily on instrumentation. Biopsies made from the rectal wall showed a picture of chronic inflammation identical with that seen in the stricture stage (biopsy findings will be discussed in more detail later).

Stricture. As a result of continued inflammatory processes and contraction of cicatricial tissue, the bowel lumen slowly diminishes, and a stricture forms. When the stricture stage is reached, patients complained of progressive increasing constipation, difficult and occasionally painful defecation, straining at stool, often of pencil or ribbon feces, bloody and pussy discharge (often present even when not at stool), abdominal cramps and bloating, sometimes loss of weight, and sometimes of perianal or vulvar swellings. Although constipation was the rule, some patients complained of intermittent diarrhea and constipation. In many cases, patients were obliged to take increasing doses of saline cathartics in order to void a liquid stool, the only form they were capable of passing through their diminished rectal lumen. Nine patients of our series underwent colostomy, 2 of their own free will and 7 because of obstruction. It is interesting to note that none of our female patients became pregnant during the known period of their stricture. Also, only two patients had any previous pelvic surgery.

On inspection of a simple uncomplicated lymphogranuloma inguinale stricture the peri-anal area appears perfectly normal with the fatty cushions practically intact.

Digital examination frequently elicited a patulous anal opening and a cone-like narrowing which tapered down to the stricture entrance 3 to 8 cm. above the anal verge. The anal cones often felt smooth, hard, and cicatricial ridges; others hypertrophied papillae, and cicatricial ridges; others hypertrophied papillae; while others presented combinations of any or all of the aforementioned findings.

In 76 patients (66%), the distal end of the stricture was located from 4 to 6 cm. from the anal opening. In 28 patients (24%) it was from 2.5 to 4 cm., and in 10 patients (9%) from 6 to 8 cm. from the anal verge.

When the opening was penetrated by the examining finger, a tubular stricture with irregular constrictions and pockets was felt. The walls were somewhat irregular and fibrous. In some cases polypoid or granular nodules were palpable. Pressure on some portions of the wall often caused the finger to break into lateral sinuses or small cavities which had been incompletely obliterated by friable adhesions which gave way to the examining finger. In most cases we were not able to reach the upper portion of the stricture. In an occasional patient, the finger passed through the upper extremity into a dilated portion of the upper rectum.

Proctoscopic examination revealed a gradually increasing cone-like deformity of the anus and rectum which led up to the stricture opening. The anal mucosa

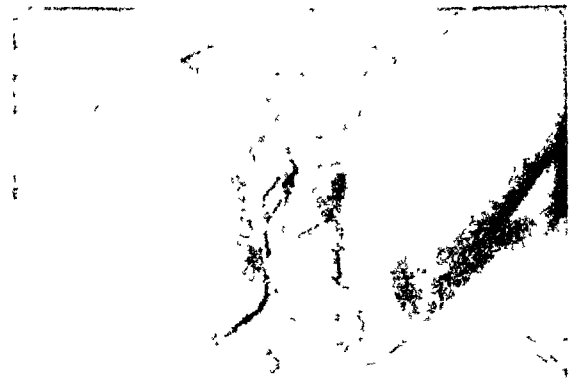

Fig. 2. M. C.: Mexican female. Rectal stricture complicated by elephantiasis of the left vulva; elephantiasis of the peri-anal area; and peri-anal granuloma with "watering-pot" sinuses.

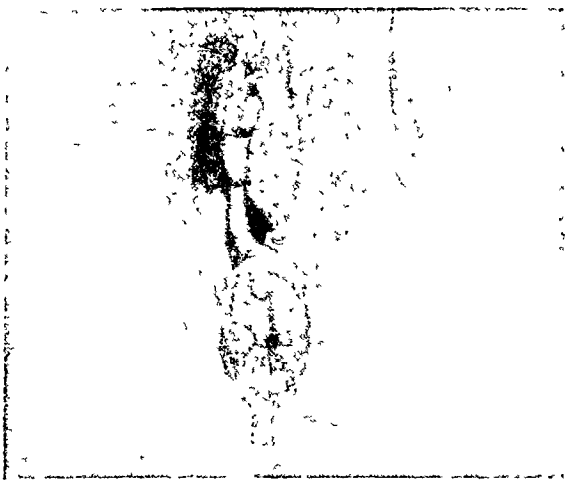

Fig. 3. H. M.: Colored female. Rectal stricture complicated by "cock's comb" anal bouquet and elephantiasis of the vulva.

was usually somewhat reddened, and presented small, ill-defined, pink-red, scattered, irregular areas of superficial ulceration. There were often blueish-white, firm scars.

A few small nodules or papilla-like strictures were often visible on the surface of the mucous membrane leading to the stricture opening as well as on the walls of the stricture proper. Frequently, congested blueish-red hemorrhoids were noted just inside the anal opening. Cryptitis, papillitis, and fissures were sometimes present.

The mouth (and as much of the walls as were visible) of the stricture presented reddened, granular mucosa, bleeding on the slightest pressure, often with firm blue-white, transverse cicatrices. Scattered areas of ulceration were present similar to those described in the anal canal. Occasionally a polyp could be seen (Fig. 1).

A blood tinged muco-purulent "cherry-juice" discharge commonly exuded from the stricture lumen. This apparently arose from lateral sinuses and abscesses which were ulcerated and infected; some of it may have come from stercoral ulceration above the stricture.

Associated lesions. In our series, sinuses and fistulae were the most frequent associated lesions found, being present in 31 patients, or 27%. In extensively complicated cases, large, thick, india-rubber-like granulomas perforated by draining sinuses were noted beside the anal opening. (Fig. 2) "Watering-pot" fistula, "cock's comb" skin tags (Fig. 3) were frequently present and occasionally vulvar elephantiasis was seen (Fig. 4).

With all this pathology, there was an anal lack of pain or tenderness of the involved parts. Also, there was rarely much impairment of the general health in spite of the apparent intractable chronicity for as long as fifteen years.

Laboratory findings. Results of Frei, Wassermann, and gonorrhea complement fixation tests have already been discussed. In 25 patients taken at random from our series, red blood counts ranged from 2,800,000 to 4,200,000. The associated hemoglobin ranged from 30% to 70%, giving in every instance the picture of a secondary anemia. White blood counts ranged from 6200 to 9350. The monocyte count ranged from 4% to 9%. X-ray studies of the chest were uniformly negative for tuberculosis. Twenty-five of our patients selected at random were given the usual type of barium enema and roentgenograms made to determine length, caliber, lateral ramifications and general appearance of lymphogranuloma inguinale strictures. The length varied from 3 to 14 cm. with an average of about 7.4 cm. Although the cone formed by the anal canal and lower rectum at the distal end of the stricture was not visualized by the films (probably due to the patulous anal sphincters so often present in these cases) a similar cone was often present at the proximal end of the stricture. (Fig. 5). In some cases an actual pouch was present above the stricture. A very important roentgen finding was the frequency of lateral sinuses leading from the stricture. (Figs. 5 and 6). In some cases actual abscess cavities were noted at the end of these sinuses. (Fig. 6). It is our impression from the clinical findings of a large number of such patients that many of these lateral sinuses do not communicate with peri-anal fistulous openings and drain into the stricture lumen proper.

Biopsies were made upon tissue from 50 of our patients selected at random. Microscopic changes were those of a non-specific inflammatory reaction. The tissues usually showed a diffuse infiltration by lymphocytes, epithelioid cells, plasma cells and polymorphonuclear leucocytes, as well as an occasional foreign body giant cell. (Fig. 7). In some, inflammatory changes were marked, whereas in others they were of a milder nature. Cellular infiltration was often peri-vascular. Many new capillaries were present. Dilated lymph channels were occasionally seen. Some connective

tissue proliferation was usually found in those cases of longer duration.

TREATMENT

Although we realize that no existing specific treatment is available for lymphogranuloma inguinale stricture patients, yet a number of medical and surgical procedures can be carried out to improve the local and general condition of these individuals.

The following treatment has been reported by other investigators with varying degrees of results. Weekly intravenous injections of 10 c.c. of a 1% antimony potassium tartrate; fuadin intravenously once weekly starting with 3.5 c.c. at the first injection, followed by 5 c.c. every other day for a total of 12 injections. Stibenyl in 5 to 20 c.c. doses intravenously on every other day. Lugol's solution has produced some improvement in a few cases. Cuprosol in doses 1.5, 2.5 and 3.0 c.c. given alternately with Stibenyl. Solganol 0.01 to 1.0 in water solution intravenously every second day. Introcoid which has been used in Hodgkin's disease is administered in 2 to 10 c.c. doses intravenously at 2 to 5 day intervals, using a total of 60 c.c. Sodium salicylate 6 to 8 grams daily given orally, keeping the patient on a milk diet or ½ to 1 gram in glucose solution is given intravenously daily for as long as 30 days, with a normal diet.

Saline laxatives, castor oil, mineral oil, various tonics, vaccine therapy, serum therapy, bouillion filtrates, hydrotherapy, finger dilatation, short wave radiothermy, X-ray and radium have been used.

Our treatment has consisted of the following medical and surgical procedures. While we have encouraged a low residue, high caloric, high vitamin diet, the economic status of all of our patients prevented them from eating anything but the usual emergency relief food. Mineral oil ½ ounce, b.i.d., was given to facilitate easier, more complete and less painful defecation.

Twenty-five of our patients, selected at random, were given from ten to twenty-five intradermal antigenic vaccine treatments by Wien and Perlstein of the Cook County Hospital Skin Department over a period of a year to a year and a half. Because these patients received finger dilatations, daily enemas, and other treatment, it was difficult to evaluate the exact effect of the vaccine therapy.

However, it was our impression that the vaccine therapy did produce some clinical improvement. Biopsies made before treatment was started and repeated after the vaccine therapy had ended showed only a change toward a more chronic type of granulation tissue. Cellular infiltration changed from a mixture of polymorphs and round cells to an infiltration by lymphocytes and plasma cells; the number of capillaries present had decreased. The essential type of lesion, however, remained unchanged.

Daily hot sitz baths seemed to be of some value. All our patients were instructed to use daily cleansing enemas of a quart of either 1/7500 potassium permanganate or 1/5000 mercurochrome solution. Such enamas served to clean out pus and infectious ma-

terial, deodorized and perhaps encouraged healing of the inflamed mucosa.

Careful finger dilatation was the only form of routine stricture stretching that we practised, and was performed once weekly or every two weeks. Graduated Wales bougies have not been used by us in these cases because occasionally such treatment results in perforation of the ulcerated gut above the peritoneal reflection, with resulting peritonitis and death. Although there has been considerable controversy as to the advisability of surgical intervention in lymphogranuloma inguinale, our experience in selected cases has been highly satisfactory.

Wien and Perlstein (3) have noted that patients with lymphogranuloma inguinale are very poor surgical risks unless first treated with Frei antigen. We have followed their suggestion and have operated only upon those who have previously received such a course of treatment.

Edematous skin tags, anal fissures, sinuses, fistulae, (anal, ano-rectal; recto-vaginal) perianal granulomas and elephantiasis of the vulva have been successfully operated upon, in about 18 of our cases. Two of our cases required posterior proctotomy to prevent complete stenosis. Operations for fistula which involve the sphincter should be done in graded stages to prevent incontinance.

Some cases heal rapidly, while others take many weeks. The constant bathing of the wound by the "cherry-juice" rectal discharge seems to prolong healing in most cases. In one case a large watering-pot granuloma was excised and healed by first intention. In this same case an elephantitio vulva was excised, and a recto-vaginal fistula repaired with good results in spite of the existing active pyogenic discharge.

We have never urged colostomy in these cases because most of the patients are young females; however, two became thoroughly discouraged with weekly dilatations and requested colostomy. Eight other patients became completely obstructed and required a colostomy making a total of ten in all who were colostomized. Two cases in our series have had posterior resections following colostomy, one done by Marshall Davison and the other by R. W. McNealy. Fig. 8 shows one of these specimens.

J. L. Jelke (4) in 1931, presented a unique drainage treatment for rectal stricture which promises to be of considerable value in lymphogranuloma inguinale stricture cases. H. C. Bacon (5) in 1934, discussed

the rationale of this operation and reported symptomatic improvement in all cases.

CASE REPORT

(This is an unusual case in which autopsy showed lymphogranuloma inguinale involving the termial ileum and colon as well as the rectum).

D. M., colored female, age 40, complained of constipation and of a purulent and bloody rectal discharge all of 13 years duration. Stools had gradually become narrow and flattened. For the past six months weakness, anorhexia, nausea, loss of weight, lower abdominal cramps, and occasional lower left quadrant abdominal pain had been present. Bilateral "pus-tubes" had been removed four years ago, according to the patient.

The patient was undernourished, moderately ill and showed evidences of marked weight-loss. Proctoscopic examination revealed a pipe-like and fixed rectal wall with a nodular constriction at 4.5 cm. which barely allowed the passage of the proctoscope. The mucosa was scarred, granular and nodular, with irregularly scattered, chronic ulcerations. Frei test was positive, Wassermann negative, G.C. complement fixation test negative, stool culture negative, RBC 2,900,000, hemoglobin 45%.

She developed marked tenderness over the lower abdomen, then one day suddenly complained of diffuse abdominal pain, became comatose, her temperature rose to 101° F. and she died twelve hours later.

Autopsy revealed the small intestines to be lined by light yellowish tan mucosa. In the terminal portion of the ileum there were three transverse defects in the mucosa, measuring up to 3 cm. in diameter. The edges of these defects were smooth and the floor was light yellow and smooth. The mucosa of the large intestine was pale pinkish gray and in the descending colon presented irregular whitish scars.

The rectal mucosa was light purplish gray in color and irregularly scarred. Scattered throughout the mucosa and close to the anus were mucosal defects measuring up to 3 mm. which extended into the subcucosa. Also seen were single ridges about 20 mm. from the anus. Throughout, the mucosa was thickened by many fibrous bands.

Microscopic examination of the rectum showed the mucosa to have been completely replaced by a very cellular granulation tissue from which infiltrations extended into the muscularis and to the outer layer of the rectal wall. The granulations were composed of large mononuclear cells, lymphocytes, plasma cells and occasional single polymorphonuclear leucocytes. On the inner surface there was a thin layer of structureless necrotic tissue. The ulcer in the ileum resembled the ulcerative lesions described in the rectum.

Hemorrhoids: Their Origin and Treatment*

By

JEROME M. LYNCH, F.A.C.S., M.D.
VINCENT HURLEY, F.R.C.S., M.D.
and
G. JOHNSON HAMILTON, M.R.C.S., M.D.
NEW YORK, NEW YORK

UNDER the general heading of hemorrhoids or "piles," the layman groups certain conditions causing itching, pain, bleeding or purulent discharge in the region of the anus. Unfortunately, many patients and some doctors proceed at once to therapy without examination. So it comes about that of the cases of rectal cancer reaching the larger clinics, 1/3 have had recent treatment—often surgical—for hemorrhoids. The "Golden Rule of Proctology" is *examination*—thorough and if necessary, repeated examination—even under anaesthesia.

Granted, then, that adequate examination has revealed the presence of hemorrhoids, we may consider the conditions properly grouped under this inclusive term.

External hemorrhoids are varicosities of the inferior hemorrhoidal vessels. They are subcutaneous and sensate.

Internal hemorrhoids are varicosities of the superior hemorrhoidal veins. They are sub-mucosal and insensate.

"Mixed piles" are composed of external and internal hemorrhoids and have all the attributes of both.

A great deal has been written about the *causes of hemorrhoids* but, in fact, they follow the Mendelian Laws. They are exactly the same as varicose veins in any part of the body. The pathology of their formation is as follows: Some degree of stasis is prone to occur in the long column of blood extending from the rectum to the liver especially since these veins have no valves. This leads to a local rise in venous pressure with increased CO_2 and decreased O_2 which, together with the sluggish removal of toxins, tends to injure the musculature of the vein. Should this condition continue, the muscle cells will soon be replaced by fibrous tissue. The occurrence of any great stress or strain or even the persistence of lesser ones will cause these weakened walls to become stretched and tortuous.

*From the Lynch Clinic, New York City.
Submitted June 1, 1934.

Fig. 1. Strangulated hemorrhoid.

In short, many of the so-called causes of piles are merely the precipitating or trigger factors which, acting upon poor-grade physiology, convert it to pathology.

Internal hemorrhoids may be prolapsed at defecation to return spontaneously or be reduced manually or they may remain chronically prolapsed. Thrombophlebitis may be present causing prolapse, swelling and pain. Gangrene and ulceration can occur or fibrosis and pseudo-polyp formation may be a late stage. Other conditions such as fissure, abscess or fistula may complicate hemorrhoids and require appropriate treatment. It follows that there is no single method applicable to the variety of conditions grouped by the layman under the heading, "piles." The following outline of treatment has proved satisfactory. *It must be remembered that the principles of surgery are alike, wherever throughout the body, one operates.*

1. EXTERNAL HEMORRHOIDS

(1) Skin tags are satisfactorily treated by subjacent infiltration with ½% novocain and or anucaine and removal with scissors in such a manner that the wound is oval and radial to the anus, continuing beyond the corrugations. Small bleeding vessels are briefly compressed by forceps, and tied, if necessary. A pressure dressing is applied and held firmly by a T-binder. The wound heals by granulation. If many tags are present there is a choice of removal at one sitting at the hospital or one at a time at weekly office visits.

(2) Thrombotic external pile or marginal subcutaneous clot is found usually at the right or left of the anus and rarely at the commisures. The etiology is somewhat obscure but considerable percentage is associated with some type of effort. There are two varieties: the single, large clot which is extravascular and the cluster of small "bird shot" which may or may not be within the lumen of the veins. Rarely, an external pile of this type is continued into a thrombosed internal hemorrhoid.

In the common, external variety, under local anesthesia with ½% novocain and anucaine, an oval of skin corresponding in size with the lump—its long axis radial to the anus—is removed with the subjacent clot. In the "bird shot" type, a similar oval of skin is excised and all the clots readily are removed with the help of pressure and bleeders are tied: packing the wound with a narrow gauze-strip, removed in 24 hours gives excellent results also. A pressure-pad with firm T-binder is applied and is removed next day. The patient continues at his occupation and merely requires supervision of the wound. The removal of an adequate oval of skin is followed by a linear scar and obviates the disagreeable tag following healing when other operative procedures are employed. In the rare cases where the external clot forms but a part of an extero-internal thrombosed hemorrhoid which extends upward several centimeters from the anal margin, the operation will be of the type described below under the surgical treatment of internal hemorrhoids.

II. INTERNAL HEMORRHOIDS

Injection treatment is indicated only for internal hemorrhoids.

The purpose of the injection is to promote fibrosis and contraction of the varicose vein and its mucosal covering. Therefore the most suitable type is the simple uncomplicated pile filled with blood. The most un-responsive ones are the fibrous, meaty types for success merely changes the characteristics of the tumor.

Injection of infected or ulcerated piles may be actually dangerous.

Patients' prejudices frequently force the use of injection treatment in some unsuitable cases, but skill-

Fig. 2. Marked prolapsing hemorrhoids.

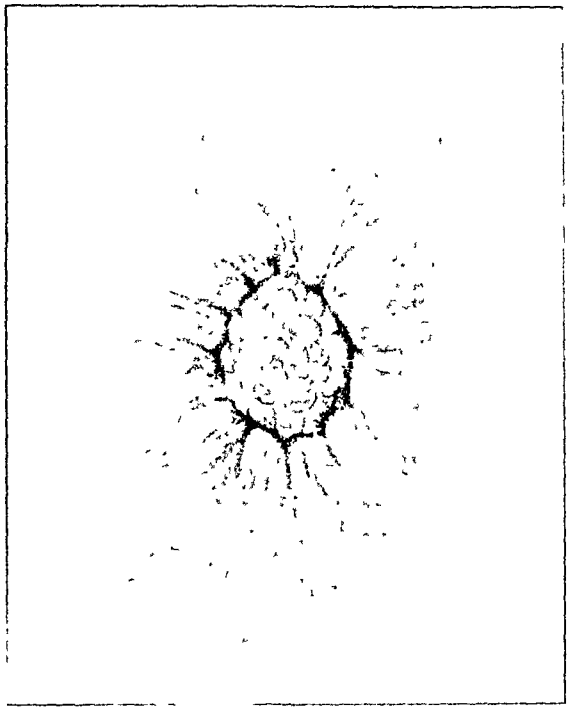

Fig. 3. The so-called strawberry internal hemorrhoid. This is the type of hemorrhoid which bleeds profusely.

ful technic permits the method to be of some benefit even if only temporarily.

Long experience has convinced us that, in our hands, 5% phenol in almond oil is the selerosing agent of choice.

The site of the injection is 2 cm. above the pile and into the sub-mucosa. The position is proven if the point of the needle is freely moveable under the mucosa. Fluid should be injected until stria are obvious and blanching has commenced. Any resistance to the introduction of the needle is evidence of the presence of existing fibrosis and contraindicates the treatment. If the hemorrhoid is polypoid, a small amount of 15% phenol in almond oil may be injected into the stalk in an attempt to cause it to contract.

The position of the patient is optional but we prefer that of Hanes'. Injections are usually given singly and at weekly intervals.

It is unfortunately true that injection is a more delicate procedure than is hemorrhoidectomy, and if improperly performed may have disastrous consequences. Therefore, it is evident that those intending to practice the injection treatment should be well equipped with the necessary instruments and solutions and should have learned the technique from an expert in the procedure.

The first injection nearly always stops bleeding or prolapse and succeeding injections usually are without incident. A series of indurations can be palpated in ring-fashion well above the anal margin in properly performed injections; endoscopic examination will reveal the presence or absence of soft, redundant tissue. If there is no evident hemorrhoidal tissue and no symptoms, the patient should be dismissed with instructions to return for a check-up in three months.

The advantages of the injection method are the absence of pain, loss of time from business, treatment is carried out in the office and there is no "operation" in the lay sense of the term. The disadvantages are the possible occurrence of sloughing or severe hemorrhage. Slough is certainly avoided by the correct placement of the injection solution; by so doing, also hemorrhage is minimized as it does not occur in the absence of slough. We encountered one unusual complication: following a single correctly-placed injection of 2 c.c. phenol (5%) in almond oil; there was a marked swelling of the rectum and recto-sigmoid accompanied by tenesmus, mild obstruction symptoms, slight pyrexia and moderate leucocytosis; there was no bleeding or discharge; endoscopic examination showed a swollen, pale, glassy mucosa somewhat resembling "bullous edema" of the bladder as seen through the cystoscope. The condition subsided in a week and was followed by obliteration of the internal hemorrhoids.

A recurrence of true hemorrhoids is found in over 10% of cases treated by injection therapy and formation of prolapsing fibrous polyps is even more frequent.

Operative treatment of hemorrhoids is more or less standardized today, the common operations being ligature and excision for ordinary piles and the clamp, excision and ligature technic in the case of large meaty ones.

Full descriptions of these technics are as follows:

Two ounces of castor oil are given 36 hours preoperatively and a cleansing enema of starch is administered at least 12 hours before operation.

We prefer to use ½% novocaine and anucaine infiltration as anaesthesia.

Any complications such as fissure, polyp, or spastic hypertrophied sphincter can be dealt with at the time of operation.

Either the left Sims' or the lithotomy position give excellent exposure.

The perianal region and anus are well painted with any of the usual antiseptic solutions and the area draped. Slight traction with the fingers on the perianal region will allow the lowest portion of each hemorrhoid to be brought into view. A curved hemostat (Kelly clamp) is introduced into the anal canal, opened and placed astride each pile, in turn, but in such a fashion that no skin is caught when the clamp is closed. Traction now is made on the clamps and the piles and the canal can be inspected. Any one clamp is selected and raised up and towards the midline;

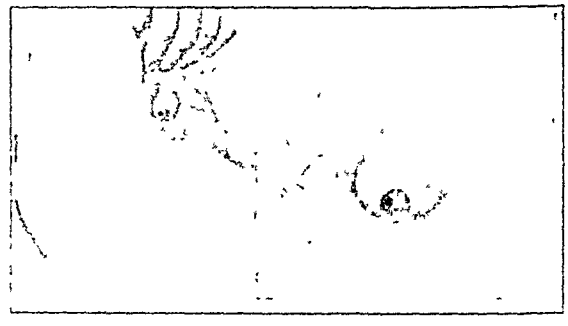

Fig. 4. Thrombotic hemorrhoid. (Reproduction from a photograph).

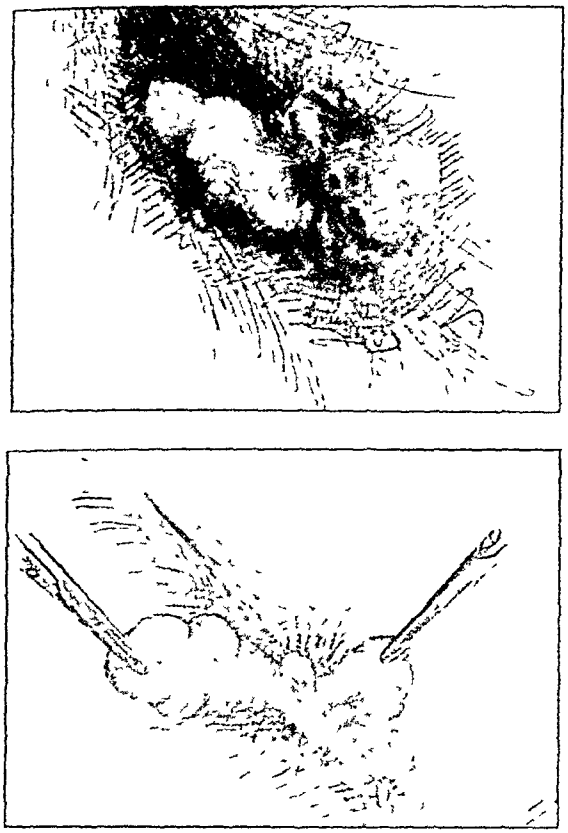

Fig. 5. Fibroid tumors of the rectum following the injection treatment for hemorrhoids.

the muco-cutaneous junction is thereby exposed and divided with scissors transversely over a distance corresponding to the breadth of the pile. The clamp now is taken in the operator's left hand and pulled up and out exposing its tip; a round-bodied, curved needle carrying a strong linen or silk thread, then transfixes the pile a short distance below the clamp-tip, the needle is removed and the thread is firmly tied proximally and then both ends are brought out, one on each side of the clamp and again tied, the ligature thus being made to lie in the raw area previously produced by scissors cut at the muco-cutaneous junction. The pile is excised leaving a generous stump. The other piles are treated in a similar manner; the area is carefully inspected for any bleeding point, the clamps are removed separately and the stumps are permitted to drop back into the rectum.

In the clamp excision and ligature technic, a heavy hemorrhoidal clamp is affixed as above. The cephalad portion of the mucous membrane with its vessels is transfixed and ligatured. The clamp is over-sewn with a running suture and slowly removed, and while the suture is tightened, leaving a linear wound.

External tags now are snipped off and any other conditions demanding attention are dealt with. A spastic hypertrophied sphincter associated with fissure is treated by division by knife in the posterior commissure. Lastly, the index finger is passed through the canal to make sure that no "diaphragm" was made during the operation. Dressings are applied to the anus and perianal region in the form of an inverted pyramid; small pads over anus, covered by pads of gradually increasing size. A large pad and a T-binder are firmly applied. Following operation, a sedative may be required for sleep on the first night but rarely thereafter.

After-care is of the simplest. Usually the dressing is changed after 48 hours and following each bowel movement. If there is unusual delay in moving the bowels, several ounces of warm olive oil are placed in the rectum and allowed to remain there over night. If spontaneous evacuation does not then occur, a simple enema is given through a catheter. Sitz baths may be employed with advantages from the third day on. The patient sits up in bed or chair usually on the third day or the fourth and may leave the hospital 24 hours later. The ligatures usually come away 8 to 10 days after operation and without pain. At this time a digital examination is made so that the surgeon may be certain no "diaphragm" has formed. The olive oil instillations gradually are diminished and finally omitted. Four weeks after operation, the anus and canal present a normal appearance; evidences of operation are minimal or absent.

It will be noticed that in the method outlined above, the sphincter is not stretched, the mucosa is not dissected up or stitched, there is a minimal amount of ligation of bleeding points, external tags are separately dealt with, skin wounds are not sutured, no special instruments are used and no tubes, plugs or drains are placed in the anal canal. Recurrences are uncommon: in our experience, less than one per cent.

Since we have perfected our technic of anaesthesia with ½% novocaine and anucaine, we have performed a large number of hemorrhoidectomies in the office with uniformly good results. Our technic varies in no wise from that employed in the operating room except that the Hanes' position is preferred. Since our anaesthesia can be made to last as many days as desired, we are under no obligation to skimp our surgery. The full operation is performed at one sitting. The patient is sent home to bed and returns for inspection in 48 hours. No sedatives are needed and the patient is able to carry on his work after the first visit.

One patient, a traffic policeman, contrary to our instructions, returned at once to duty and experienced no pain whatsoever.

Note: We cannot express too highly our gratitude to Dr. R. V. Gorsch for this anaesthetic which has opened up an entirely new field of operative proctology.

SUMMARY

External and extero-internal hemorrhoids are treated by surgery only.

Internal hemorrhoids may be injected or excised.

Hemorrhoidectomies may be performed in the hospital or the office.

Contrary to our youthful statements, all manner of plugs and tubes are contra-indicated in hemorrhoidectomy.

The Significance of the Icterus Index in Proctological Disorders

By

R. V. GORSCH, M.D.†
NEW YORK, NEW YORK

THIS preliminary communication is designed to emphasize the significance of icterus index in rectal disease, as distinguished from the worth of the estimation in hepatic or hemolytic disorders. We desired to determine its value, if any, as a diagnostic test indicative of the presence or absence of infection harbored in the rectum and adjacent structures; also whether, by this test, the severity and chronicity of rectal lesions can be determined. In short, is increase in the icterus index in proportion to the severity of the infection and does it return to normal with the eradication and healing of the lesion? Such a determination would be of great value to the proctologist, especially in certain clinical entities whose etiology is either diverse or unknown; for instance, pruritis ani. A fairly exhaustive search of the literature fails to reveal any investigation along the lines embodied in this paper.

Our incentive for this study came about accidentally. In the routine blood report of a case of pruritis ani, we noted that the icterus index was above the normal level although clinically there was no evidence of disorder of the liver or blood. A repetition of the test in many other patients with the same condition showed uniformly high results. An unselected series of patients from Dr. Frank Yeoman's clinic at the Polyclinic Medical School and Hospital then was subjected to the test and again in the majority of those with anorectal disease there was a concentration of bile pigment higher than the accepted standard.

The term *icterus index* is used merely to express the degree of yellow color imparted to the blood by the bile pigment, bilirubin. Briefly stated, bilirubin is an intermediary substance formed by the liver from the food, the body cells, and the liberated hemoglobin, and excreted from the blood. When it reaches the intestine, the bilirubin in the bile is broken down by the action of intestinal bacteria and forms urobilin, which is responsible for the brown coloration of the stool. Not all of the bilirubin is thus destroyed; some of it is reabsorbed into the blood, giving the serum a yellow color. The icterus index measures the intensity of color which this bile pigment imparts to the serum. The liver, however, is not the only source of bile pigment; it is produced independently by the reticulo-endothelial system (spleen, bone marrow or blood vessels) (1). Bilirubin from the latter source, however, is also excreted through the liver from the blood.

It is stated (2) that the normal figure for the icterus index (the intensity of the yellow color imparted by the bilirubin to the blood in the absence of hepatic or hemolytic disease) lies between 3 and 5. The increase of this pigment to 6-15 is claimed to denote latent jaundice, and at and above 15 the clinical symptoms (yellow color of skin and conjunctiva) are apparent. Carotene sometimes, although rarely, must be taken into consideration but is omitted from this discussion.

Heretofore the concentration of bilirubin in the blood has been of value chiefly in determining the severity of jaundice produced by excessive hemolysis of red cells from any cause, and loss of function of the liver cells from toxic or obstructive lesions. In either case the liver was unable to excrete bile (bilirubin) into the intestine, with the result that it was retained in the blood, causing clinical jaundice. Occasionally also it was used to determine the effect of arsenicals on the treatment of syphilis. This point is stressed because, to the best of our knowledge, none of our patients showed any clinical signs of the above mentioned disorders.

To explain the increase of bile pigment shown by the icterus index in our studies we offer tentatively the following theories. We believe that infection involving the vascular bed (phlebitis?) of the rectum or lower colon is carried by lymphatic extension to the liver, producing a hepatitis sufficient to interfere with the pigment excretory function of the liver (latent infectious jaundice). Another explanation is that the excess bilirubin is formed by the reticulo-endothelial system, chiefly the vessels of the hemorrhoidal plexus. It is generally conceded that these cells are strongly phagocytic and have much to do with the breakdown of the hemoglobin into bilirubin. This may be explained on the basis of the great proliferative capacity of the cells of the reticulo-endothelial system.

We are not prepared to state, as yet, whether this condition is confined principally to the vessels of the hemorrhoidal plexus following infection. Whatever the cause of this oversecretion of bilirubin, the liver is apparently unable to excrete the excess as shown by an icterus index above the normal.

One more point to be clarified is the value of the icterus index as a means of determining the amount of bilirubin in the blood. On this subject the literature reveals that opinion is by no means unanimous. Some reports seem to show that the quantitative van den Bergh test is considered more reliable; we report a few such tests. Ottenberg (3), however, maintains that the icterus index is more accurate in determining the level of the blood bilirubin and also its variation from day to day, which is even more important. For

Submitted October 17, 1936.

this reason, and on account of its simplicity, he prefers it to the van den Bergh test.

A summary of our findings returned from estimating the icterus index in patients with proctologic ailments, shows it to be above the normal: in 16 (87%) of patients with pruritis ani, mostly of the third degree; in 7 of 9 patients (80%) with internal hemorrhoids accompanied by various degrees of infection, ulceration and prolapse; in all of eight with fistula in ano; in 5 of 9 patients (55%) with fissure in ano five (55%); in 4 of 6 patients (75%) affected with external thrombatic hemorrhoids.

Of the total of 52 cases studied, 40 exhibited an icterus index well above the accepted normal figures; that is, of an unselected consecutive group of rectal disorders, 81% revealed abnormal figures in patients who clinically gave no evidence of disease of the biliary or hematopoietic system. (Twenty-one patients were omitted from this series because the rectal findings were too diverse to be classified into groups, but of these the majority gave abnormal icterus index readings).

The tests all were performed by one individual, an experienced technician in the hospital laboratory, thus obviating the chance of personal error. The technician did not know the purpose of the tests or the clinical findings in the patients referred to him.

One of our many future problems is the matter of control with normal patients whose anorectal apparatus has been thoroughly examined and the foci of infection excluded. Other measures will include a thorough medical examination to exclude disorders of the blood from causes other than the biliary system; determination of bilirubin, blood cholesterol and sedimentation rate; and liver function tests with intravenous Azorubin S with recovery of the dye by means of an intra-duodenal tube according to the method perfected by Dr. Samuel Weiss (4, 5, 6) in the Gastroenterological Clinic of the Polyclinic Medical School and Hospital.

CONCLUSIONS

We wish to emphasize that in this report our purpose is merely to indicate that a large percentage of patients with rectal infections reveal an icterus index above the accepted normal (generally considered as 3 mgm. per 100 c.c. of blood).

We hope to carry on this work in more detail and reach a definite conclusion for or against the value of this test in proctological disorders. In the past, practically all the work along this line has presupposed the presence of disease of the hematopoietic and biliary systems without consideration of other cause for an increase in the serum bilirubin.

CONCERNING THE ENIGMA, PEPTIC ULCER

(Continued from the September, 1936 issue)

B. *Therapy limited by the nature of ulcer pathology.* From the previous discussion, it would seem that, in respect gastric ulcer, non-surgical treatment confronts the problem of managing a *mucosal* defect in not more than 20% of patients, taken consecutively of a group which had symptoms and signs so urgent as to warrant surgery. It may be stated, that often such mucosal lesions are transient; they represent but stages in tissue defense and repair.

Our observations on groups of gastric ulcers exhibiting mucosal defects which did *not* go on to surgical intervention, indicate that whether or not they were treated, each ulcer possesses a pathologic life-cycle, highly individual in character. Often, the mucosal defect heals itself in strikingly short time. If one is to place any reliance upon the "acid-response" test suggested by W. Palmer, and improved by Hardy, in even extensive lesions, mucosal epithelialization may occur in 24-36 hours. But although occult blood may be absent from the gastric content and free HCl and pepsin be "normal" when there has taken place complete epithelial repair, the patient's symptoms rarely disappear unless gastric peristalsis is absent or at a minimum rate or degree of intensity. In such circumstances, it becomes evident that pain, as well as other symptoms, are due not to the "corrosive action" of gastric juice, to hyper-pepsia or to foods which locally "irritate" the "ulcer," but they depend upon excitation of mural reactions at the site of the pathology in the wall. We have observed instances where large, blood-seeping, mucosal areas existed and the gastric content was abundantly rich in acid and pepsin, but cessation of peristalsis, upon rectal feeding or the exhibition of antispasmodic drugs, was followed by complete clinical comfort.

Of the remaining ulcers of the group being discussed in this communication, (80% of the group total) *i.e.* lesions not presenting the mucosal *facade* so generally thought of as concomitant with this gastric affection, the actual therapeutic problem was the management of *mural* pathology of variable and varying extent, ranging from more or less complete attempts at plaque-like, scar-formation to roughly, wedge-shaped areas; in general the base of the wedge lay toward the submucosal tissue. Pathologically, these wedge-shaped areas exhibited destruction of normal, mural structures side by side with disordered blood—and lymph—stream architecture, and early or late attempts at the fibroblastic proliferation of repair. Such pathologic foci most commonly were confined within the stomach walls but, as mentioned above, frequently enough, they penetrated to and included the serosa

("soldier-spot" lesion); in a number of cases, neighborhood structures were involved; in a few instances, there was "perforation"; when such occurred, there was a *serosal "ulcer facade"* to the lesion; the "ulcer's" base then was formed by the submucosa. If one may judge from the literature, considering gastric "ulcer" as having its "open" aspect at the *serosal* surface of the stomach's wall, is a novel conception, certainly with respect non-surgical therapy. However, such condition not infrequently is the finding. It is quite as legitimate to regard "ulceration" as occurring at the serosa as at the mucosa—and certainly is warranted by the facts. One's view-point only requires changing from that which some seventy years have established as a "tradition" in respect "peptic ulcer." Our study of a representative group of operatively proved ulcers, demonstrates that, in 4 of 5 such, the progression of the initial mural pathology is *towards the serosa* and not *towards the mucosa*. The mucosal involvement definitely is a pathologic accident; it is a complication during the development, and, the attempts at repair, of the mural focus, when submucosal and then mucosal tissue-nourishment is interferred with. It is evident that the mucosal "ulcer"-aspect of gastric ulcer does not begin, and is only secondarily maintained, as a consequence of chemical action or food traumata. Just as ulcers present on the endocardium, in bacterial endocarditis, later do not produce the mural myocardial plaques which the heart exhibits as "soldier-spot" defects, at places where there has been localized, myocardial destruction and subsequent repair by scar, so gastric ulcer, initially, does not begin as *mucosal death* from intra-gastric causes and the mural pathology does not appear as a consequence of what has occurred in the mucosa. *The mural lesion is the primary malfunction;* from that, depending upon its nature and extent, arises the so-hastily named "peptic" mucosal defect of ulcer-form.

While many constitutional, metabolic, toxic, bacterial or neuro-psychic agents or mechanisms may be responsible for initiating the mural lesion, evidence is strong that their action is exerted through the blood and lymph vessels in the stomach wall. It is evident that some mural lesions occur as a consequence of *arterial, arteriole* or *arteriole-capillary occlusion* (sclerosis, plugging by clot, rupture, prolonged spasm); others represent *venous stasis* prolonged to a degree sufficient to stop blood-flow; *lymph stasis* likewise may be so complete that tissue catastrophe may follow when this "third," and little considered circulation, no longer is possible. Bacterial deposits can be considered "accidental" or secondary in the great majority of gastric ulcers. Future studies made with the object definitely of analyzing the minute pathology of peptic ulcer may enable us to distinguish the various ulcers in relation to the nature of circulatory block; such studies, strangely, rarely have been made. It is more than likely that, depending upon the nature of the initial circulatory interference (arterial, venous, lymphatic) ulcers vary as to clinical course. A phase of ulcer observation in regard to etiology, should be the careful study of the capillary circulatory bed and observations on the general lymphatic state. Certainly, such ulcers as have a tendency to early and free bleeding would appear to depend for their initial mural pathology upon arteriole rupture. The seeping ulcer of the patient with external or constitutional evidences of a tendency to prominent veins and venous stagnation, may arise from local, venous stasis; such ulcer seems to run a course relatively free from the acute, sudden, copious hemorrhage-accidents common to those in which arteriole blood-flow is at fault.

C. *The Effect of Ulcer Development, Extension and Repair Upon Gastric Function as Related to Treatment.* Not often does non-surgical ulcer management as practiced concern itself with any consideration of at what stage of healing may be the ulcer. The patient is *fitted* to such "standard" regimen as that on which the clinician has been "sold," irrespective of whether mucosal epithelialization has or has not already occurred, or a mural lesion is progressing towards the serosa, or a tough scar deforms the stomach's contour or blocks considerable of the pyloric channel, or a crater-diverticulum interferes with orderly peristaltic function or a recent hemorrhage, (in association with arteriosclerosis and actual or potential hypertension) has given warning of impending and probably fatal bleeding or perforation. Almost universally, the same kind of management is exhibited as when the only lesion exists is a mucous "erosion" quite capable of healing itself if allowed to. Pathologic considerations all too frequently give way to those rule-of-thumb therapeutics which were proposed many years before exploratory surgery and examination of pathologic tissue were possible. And, even though responsible evidence proves that, in peptic ulcers unassociated with gastric stagnation, the titre of gastric juice does not exceed a vaguely theoretic "normal," the vast preponderence of "treatments" has, as its basic idea, the "neutralization" of free HCl so that "corrosion" of the ulcer area may cease. (Who, indeed, is able to say what degree of gastric acidity *is* or *is not* "normal" in health or disease, for any given subject? Studies of individuals absolutely free from dyspepsia, have returned acidity readings far higher than those recorded for patients with proved ulcers; observations after psychic, emotional or physical effort have recorded acidities exhibiting extraordinary increase; lastly, it is admitted generally, that our laboratory methods for estimating acid values are wide open to criticism).

Of the series of ulcers being discussed, where symptoms were so distressing as to warrant dangerous surgery, in not 20% was epithelial protection lacking at the ulcer site. It is but pertinent to ask, what effect upon mural defects, now quiescent and again progressive, could ant-acid therapy exert? Apart from a diet of limited quantity which permits periods of gastric peristaltic quiescence, lavage which has a similar effect and bed-rest which favors circulatory equalization, medicinal agents as *positive* healing substances, are not far from being of about as much significance as is the reading "page 123" of the christian (?) science (?) "Manual," the ground bark, dried snake-skin and powdered guano mixture of the can-canning, South Sea Island Medicine man or the flashing colored lights and the mystic whirl and buzz of the machines devised (certainly, with a sardonic chuckle at "what fools, etc.) by the late Abrams out in the exhilerating and reason-shaking air of ever-curious California. Just as it is the present vogue to ascribe the pathologic mural changes which precede the development of the mucosal lesion of ulcer, to "emotional instability," the "kinetic drive," the result of "stress and strain of modern living" and the like, so, in the non-surgical attack upon ulcer, it appears that much in our aramentarium depends for its

efficacy upon the psychic effects of the routine established: the taking of "*this* at 8 and *that* at 10" and the consolation which may be brought by impressive and solicitous physicians—not forgetting the ministrations of nurses who well know how to cojole and to swish their crinoline. That these observations are warranted is demonstrated by the recent experiments of Flood and Mullins (*Am. Jour. Dig. Dis. and Nutrit.*, Vol. III, No. 5, July, 1936, p. 303): hypodermatic injections of sterile salt solution proved quite potent to assuage pain and discomfort; quite as potent as an expensive and widely popularized "research" preparation or of even commonly used drugs and limited diet. Such experiments certainly should compel serious thinking among physicians, particularly among gastroenterologists. They should lessen the temptation to fit patients to "standard" routines of treatment; they should emphasize the fact that, in 80% of proved ulcers, epithelial protection already has been accomplished through "natural" reparative effort; they should lead to a strict scrutiny of what, pathologically considered, in *each* ulcer subject, actually is to be treated; they should bring support to the opinion that whenever — by whatever safe agencies — the motor function of the stomach can be controlled to a degree that one controls the movements of a fractured leg-bone to secure union, so, proportionally, there is given the greatest opportunity for the normal healing of gastric lesions. Surgeons are familiar with such facts: after extensive gastric surgery, they keep stomachs free of all foods and drugs for several days. We have examined a number of stomachs which have been subjected to operations, when the patients have died from exhaustion, embolus, etc. As early as 27 hours after major surgery, we have observed such complete epitheliazation of great areas of the mucosa that, aside from support to muscle coats, there was no need for stitches to prevent gastric leakage.

D. *Gastritis and Gastric Ulcer.* Fortunate it is, that many so-called "ulcer" patients are non-surgically managed for only mucosal "erosions" or various types of "*gastritis.*" While the whole subject of what constitutes *true gastritis* is in flux, yet it can be said that in none of the vaguely delimited "types" of gastritis has it been shown that such lesions lead to or favors the development of true gastric ulcer. In other words, as has been emphasized above, however great may be the departures from the normal in mucosa or submucosa in the conditions loosely grouped as "gastritis," unless such be accompanied by a localized *mural* defect, classical peptic ulcer does not supervene. Even in those instances of localized or general infectious or suppurative "gastritis" (a rare occurrance) abscess-like formations are not followed by any lesion even suggestive for gastric ulcer in gastroscopic or roentgen appearance, in clinical course or termination. *Initial mucosal lesions tend to remain mucosal* or *submucosal;* they tend to heal without distinct *mural* pathology such as one finds in true ulcer. A suggestive distinction is possible: in instances of local, severe, traumata by intragastric burns (cauterization, hot fluids and the like), the resultant damage rarely penetrates the submucosa; it tends to heal rapidly and completely; on the other hand, when severe body-surface burns occur and gastric ulcer, frequently of hemorrhagic type appears, the lesion heals slowly. In such circumstances, pathologic studies reveal true mural lesions such as accompany peptic ulcer of etiology other than body-surface burns. One may note localized or multiple mural areas, in which arterial (perhaps venous or lymphatic?) circulation is interrupted by emboli, by capillary rupture and extravasation of blood; the tissues, lumen-ward, then necrose, are digested by any proteolytic agent present (gastric juice, regurgitated duodeno-jejunal secretions, bacteria or even the peptid-splitting enzyme normally present in the blood serum itself (Smithies, F., "A Peptid-splitting Enzyme in Normal Blood Serum, *N. Y. Med. Jour.*, 1913, 98:619). In many instances of "gastritis" accompanying gastric ulcer, the so-called "gastritis" represents little more than local or general variations in submucosal or mucosal blood-flow, combined with such secondary anomalies as arise when epithelial structures are endeavoring to preserve themselves and to continue functioning. Such being the case, one ceases to wonder at the so-frequently changing pictures of "gastritis"; certainly, recognition of these basic facts should cause hesitation with respect attempting to construct any dependable classification—clinical or pathological—of types of gastritis. The evidence seems clear that gastritis is not a fore-runner of true peptic ulcer.

E. *The Chronic Ulcer with Extensive Scar Formation.* It should seem not necessary to emphasize that, with respect the scar-tough, deforming, obstructing or "penetrating" forms of mural lesion, whether or not such have lumenal *facades* of ulcer type, (unless the lesion has a luetic etiology) no drugs with which our profession is familiar can be introduced into the stomach and there be capable of exerting the slightest positive therapeutic effect. Not that gastric rest —motor and secretory—combined with lessening the work-load of the viscus and the exhibition of acid-neutralizing drugs may be not followed by improvement in the degree of the patient's physical comfort. It is common knowledge that patients do experience less distress on such regimen. However, it should be recognized and, frankly admitted, that such restoration of well-being does not mean that the mural pathology has been affected positively by the drugs given. Indeed, all clinicians have observed instances where most serious and lamentable "complications"—as gross or fatal hemorrhage, acute perforation—have occurred when patients were symptom-free. These dreaded happenings are all too-commonly recorded as intruding upon what appeared to be satisfactory treatment results.

Cessation of symptoms upon the exhibition of diet, rest and antacid drugs doubtless is due to the fact that the peptic ulcer lesion has a highly individual life-cycle. Initiation of the mural lesion, advancement of tissue destruction to include submucosa and mucosa, with resultant mucosal ulcer *facade,* follow an orderly course. The extent of tissue destruction depends upon the location, character, persistence and size of the mural defect. Tissue lysis and reparative efforts follow in a regular fashion; the endeavor ever is towards histologic repair, in kind or as fibrous scar. When patients are acutely affected—whether or not there is mucosal destruction—they seek medical or surgical aid. It follows that, provided tissue destruction does not give rise to copious hemorrhage or perforation of the stomach's wall, any therapy which brings "physiologic rest" (Smithies) to the viscus, aids the normal reparative effort such as is common in any lesion, anywhere, when structure is destroyed

and yet neighboring parts retain their native ability to heal. One need not emphasize how, in such circumstances, many forms of therapeutic procedure obtain vogues as being "specific." All clinicians are familiar with the "specific" therapy which, from time to time, has been advanced for the management of typhoid fever, pneumonia, liver cirrhosis, nephritis, myocarditis, with or without coronary disease. The common factors of usefulness in all the varied therapy of these affections have been those concerned with general care, rest, relief of symptoms, watchfulness. Particularly is the analogy between ulcer management and degenerative heart disease a close one. Just as in the sclerotic, vascular and myocardial affections do we observe relieveable, recurrent, acute episodes, so, in peptic ulcer, we observe mural pathology, now active now quiescent. In the active phases, there occurs stomach (or duodenal) dysfunction, relief of which is desirable; but symptom-relief actually is not positively *curative* towards the initial or the progressive mural pathology. Nor can one say that "recurrences" always mean that the original "ulcer" again recrudesces. The studies of Dr. Gregory Cole appear to indicate that "recurrence" often means the appearance of a new ulcer or the marginal extension of the initial lesion after the fashion in which the original ulcer arose. One sees the effects of similarly-acting pathologic sequences in hearts where myocardial destruction and repair are the consequences of vascular faults.

We have no quarrel with the various regimens exhibited in the management of gastric ulcer, provided the clinician has an honest appreciation of his limitations and those of the problem confronting him. Our stand is that the clinician should realize that relief of symptoms has little positive significance with respect the pathologic processes which are present in the stomach's wall. He should recognize that his therapeutic agents, (particularly drugs) except in instances of lues, have no "specific" or direct action. Thinking pathologically, not chemically, grouping his patients on the basis of probable mural pathology present in the individual, ever bearing in mind the significance, upon function and visceral integrity of pathologic anomalies murally located — all such considerations will result in less loose thinking, less faddism, less waste of effort in searching for "specific" cures, and on individualization of therapy according to the gross and microscopic nature of lesion and the constitutional type of patient. So too, will it become evident that there should be a continuous form of management, *between acute episodes*, whose supervision may prevent or anticipate future incapacitation or life-taking complications.

F. *"Ulcer-phobia"* dominates many hosts. It has a serious bearing upon ulcer healing, upon economic usefulness, upon life as a pleasant and to-be-desired experience. Knowledge of the nature of the mural pathology present in the individual gastric "ulcer," should enable the physician to maintain an optimistic attitude, an attitude which readily is conveyed to patients. Barely 10% of peptic ulcers are associated with crucial crises. Surely, possessed of such knowledge, both patient and physician better can face the future. The serious complications demand early surgery. At the hands of qualified surgeons, the operative mortality, approximately, is 3%, when even the most aggravated lesions are included. The post-operative digestive morbidity is not 10%; this is becoming reduced as surgeons select their operative procedures to fit each ulcer and do not fit all types of ulcer to a rule-of-thumb procedure as is now, alas, so common in "medical" management. Only thoroughly competent surgeons—skilled in pathology as well as in technical manoeuvres — should perform operations upon the stomach: the "venturing" of the improperly trained has no place in visceral surgery. So, too, the non-surgical management should be in competent hands. Undoubtedly, at present, many functional gastric affections are being treated as ulcers, thus greatly adding uncertainty to statistics regarding "cure." In the presence of real ulcer, simply knowing the "steps" of a popular mode of management, does not justify the practitioner who has not a sound medical or gastro-enterological training in taking charge of patients. That this is so, is proved daily in any important clinic, by observing the serious situations which arise from hemorrhage or perforation during the course of fit-the-patient-to-a-formula types of managements. While there has been undue alarm over malignancy and its relation to benign, chronic, gastric ulcer, clinicians of experience, nevertheless, all too-often, observe patients arrive at stages of inoperable cancer during medical management by so-called "standard" forms of treatment. When the physician is treating accurately proved gastric ulcer, his attitude ever should be critical. Relief of distress, while a happy event to the patient, should not lull to apathy the medical attendant. By all means available —physical examination, laboratory studies, roentgen observation, gastroscopy—he should endeavor to secure unbiased knowledge not alone as to epithelialization of the lumenal ulcer-*facade* but as to the changing status of the primary, mural lesion. *This demands appraisal of the patient who has the ulcer even more than treatment of the ulcer itself.*

Frank Smithies, Chicago.

INTRODUCING VOLUME IV

THE *American Journal of Digestive Diseases and Nutrition* completes its third year with the current issue. During the past twelve months, numerous readers have given the Supervising Editor valuable criticism. The front page title is to be cast in a simpler type; this probably will appeal to most readers. All "section" divisions are to be done away with, except Editorial, Book Review and "The Clinic," so that major contributions will run in undisturbed sequence. About one-third of our correspondents wanted the page-size of the Journal somewhat reduced, but since such a reduction would interfere with the mechanical requirements for advertisements (a feature of essential importance to the Journal's survival) it has been decided to maintain the present distinctive format, especially because most readers actually like it. Taking our cue from the Journal of the American Medical Association, an attempt is being made to interest some advertiser in a front cover position, as has been suggested by many readers.

Generally speaking, excellent progress has been made by the Publishers, although, as yet, no reduction of their deficit has been found possible. The Publishers are holding an ideal before them and are trusting to the essential merits of the publication for its growth. As with the Editorial Council, so with the

Publishers, the motivation is the production of a clear-cut, serviceable archive in a special field, and there can be no doubt now of the permanency of the undertaking. No apology is offered, however, for exhortation to our readers to form the habit of making proselytes: we need greater circulation of the right kind; but the Publishers will not employ high-pressure sales' methods to secure such.

Manuscripts of increasing importance and quality continue to flow in from distinguished clinicians and investigators. Reprints are being furnished at cost to authors. Advertisers claim to be receiving unusually good returns from their accounts, due, no doubt, to the fact that the *Journal* is read largely by men in "key positions" in the profession, and men who recognize the *Journal's* sincere obligations to the firms who advertise in this periodical. The extremely high renewal percentage by subscribers indicates that the *American Journal of Digestive Diseases and Nutrition* already has become a "family affair," nay almost an institution in America.

While ground for gratification at present exists, we feel that there is much room for progress in all departments: constant refinement of format, contributions of still higher order, greater brevity by authors, even closer cooperation from readers than at present. In a very real sense the *Journal is yours.* We desire, and need, your complete cooperation as we launch the next (March) issue, Volume IV.

Beaumont S. Cornell, Fort Wayne.

SECTION IX—*Book Reviews*

(This section is open to contributions from any medical reader, whether or not a member of the Editorial Council).

"The Art of Ministering to the Sick," by Richard C. Cabot, M.D., and Russell L. Dicks, B.D. The MacMillan Company, 1936, 378 pages, price $3.00.

THE authors have written this book with the hope that it will be of interest to doctors, nurses, social workers, and to the sick themselves, as well as the ministers to whom it is addressed primarily. Each of the authors is chiefly responsible for certain chapters, whereas in several their ideas are intermingled so closely that one cannot tell which of them wrote the various paragraphs. This is somewhat confusing to the reader who frequently asks himself the question: "Who wrote this?" It is apparent, however, that the views of the two are in such complete harmony as to give the question little significance. An attempt has been made to follow a definite plan of organization, but it has succeeded rather poorly, due, perhaps, to the fact that the various aspects of the subject interweave so closely that it is difficult to separate them so clearly and sharply as would be desirable in an ideally analytical exposition. Nevertheless, regardless of its organization, the subject matter is valuable.

It is perhaps significant that it is addressed primarily to ministers, the authors obviously conceiving of the Christian minister as one who plays the role of an intimate friend and confidant rather than that of a formal high priest. It is rather surprising that so little has been written on this relationship between the pastor and his parishioners. The topic is a timely one and the book fills a real need, particularly as it deals with illness, death, and bereavement.

Recently an interest has developed in the provision of "clinical" training for theological students during the summer months between the terms of study. A description of this undertaking is included in the appendix and may be mentioned here because it illustrates the scope of the book. At present the agencies sponsoring such opportunities for clinical experience are the Council for the Clinical Training of Theological Students and the Earhart Foundation, both of which insist that the student be under the institutional supervision of some member of the medical staff and more particularly under the theological supervision of "an ordained minister who has had special training to prevent the student from being busied chiefly in social service or in medical, psychiatric or recreational activities, to hold him primarily to a study of his own professional responsibility and to instruct him in the resources of the Christian religion for meeting the needs which he sees." Both of these agencies are said by the authors "to be strongly opposed to the practice of psychiatry or to the use of psychoanalytic technique by the minister, although it is believed by members of both organizations that the minister has much to learn from the New Psychology. It is believed by the leaders of these two organizations that churches should not establish clinics for the mentally ill but should cooperate with other agencies to make the service given by the psychiatric clinics more fully available to the community."

The book opens with the question to be answered by it, namely: "Has the Protestant minister of today any good reason to visit the sick?" In the first chapter the three aims calling the minister to the sickroom are listed as "(1) to counteract the evils of specialism, (2) to give a devotion such as only religion can permanently inspire, (3) to care for the growth of souls." The first aim, that of counteracting the evils of specialism is made necessary, apparently, by the fact that modern doctors "lack the time, the interest, and the skill to make the social and spiritual diagnosis, or to give social and spiritual treatment to their patients." The authors concede that they would prefer to see doctors treat all of their patients' ills were it practically feasible for them to do so, rather than to turn over some of them to the nurse, social service worker, or minister. The ideal apparently is an all-around-man, such as Dr. Grenfell in Labrador. It must be admitted, in the opinion of the reviewer, that modern medical education does not produce and does not aim to produce this type of a doctor, for the emphasis is placed upon facts and objective data pertaining to the body, its organs and functions. On the other hand, all great physicians learn from experience the importance of these other factors, but in our present age of specialization we may perhaps agree,

therefore, with the statement attributed to Dr. James H. Means: "I believe the patient should send for his minister when he gets sick just as he sends for his doctor." The authors note some difficulty in attempting to delimit the precise sphere of the minister, but they succeed in making perfectly clear that it is one of assisting the physician, the nurse, the patient, and the family, of getting them all to work together under the supervision of the doctor for the good of the patient, and more particularly, that "it is the minister's duty to rouse the great energies, certainties, and faiths of the Christian religion." One's opinion of this goal will depend, of course, upon his own philosophy, but it must be conceded that for those who do accept the Christian faith, there is a definite opportunity and need of this type. For those who do not accept the Christian belief, there is still an opportunity, according to the authors, for the minister to be of definite assistance in helping the patient to develop the courage and hope with which to overcome the suffering and the inevitable ordeals of illness. There is ever an opportunity for the minister to inspire courage and "to devote himself to the growth of souls (in the broadest sense) at a time when pain, sorrow, frustration, and surprise bring experiences that invite a new start in life."

The chapters on preparation for such work emphasize the importance of personality and include pertinent advice with regard to one's conduct in the sick room. Medical students are inclined to look upon these attributes of the practitioner more or less derisively as the "bedside manner" or "personality" of the physician as opposed to his scientific knowledge. Dick points out that much of the important work of the world depends "upon personality not only in medicine but in all fields of human endeavor, that personality in the broad sense of the word includes knowledge, insight, skill, interest, hope, devotion." Adequate preparation is, therefore, essential. In the development of this subject Cabot has contributed two practical chapters dealing with the problems and difficulties likely to arise in the institutional care of the patient and the characteristics of doctors, their peculiarities, their points of strength and weakness.

In connection with the situation which the minister must face, Mr. Dick discusses at some length the conditions considered by him to be five forms of spiritual backsliding: loneliness, boredom, fear, bitterness and the morbid obsession of guilt." His approach to these problems is quite sane and applicable in the main to both the Christian and the non-Christian. Pain is divided into physical and mental suffering, the latter being less endurable than the former. While admitting that physical pain is almost always pure loss, four mental habits are suggested which may help us to escape bitterness and a loss of faith in a time of painful crisis: (1) Get beyond the childish impulse to place personal blame on some person or object for every difficulty or hurt. (2) Learn to see that nothing happens to you as a unique experience leveled at you alone by some special design. (3) Learn after each experience of pain to sum it up and discover what value you can wrest from it, and (4) Learn how evanescent pain is. Dr. Cabot is able to find real value in mental pain, however, for he sees it as an essential part of the growth process. The sense of growth or growth tension is seen as man's only real need on earth. "The sense of success and the sense of failure are signs that we are off the path of the growth process." When one is really on the path of growth "pain and pleasure, the awareness of success or of failure, die down to subordinate notes in the theme of growth." The meaning of the word "growth" is further amplified in the appendix, "growth as we use it connotes all that is morally good and all that is morally good must appear as growth. . . Growth takes place in character, not toward character; in wisdom, not toward it. There is no goal which we approach." Dr. Cabot's discussion of evil, of the problem of Job, is theological and is based upon his "fighting faith that there is an explanation for much that we cannot explain, that God permeates all with his plan, that "the universe must be under a plan, and that (that) plan could not be bad else it would contradict itself, as it seems to do in evil, and so be no plan at all." In the chapter on "Vis Medicatrix Dei" Dr. Cabot pays tribute to the healing power of nature, although he prefers to interpret the phrase as meaning the goodness of God. He then, in the following chapter, concludes the presentation of the situation with which the minister will be confronted by a series of brief but very pertinent comments on twenty-one different diseases and conditions, such as pulmonary tuberculosis, cancer, fractures, childbirth, adolescence, and insanity.

The third section deals with the primary needs of the minister in the practice of his art. It is felt that he needs a bag, like a doctor or a lawyer, which should contain "some Protestant equivalent for the Roman Catholic priest's stole, wafer, and oil," if there be such; a notebook, for the events of each ministerial visit should be noted, remembered, and to a certain extent planned just as are those of the physician's visit; small gifts and surprises, preferably loans, which will provide new trains of thought and leave fresh after-images for the patient's mind, and most important of all, perhaps, ideas for the mental kitbag must be packed, too. The authors emphasize the care which doctors and nurses should take in their prescription by literature, because patients have a high regard for their opinion and may be introduced inadvertently to an undesirable course of reading. The great importance, however, of a desirable reading program, as pointed out by Dr. Webb in his charming essay on "Prescription by Literature," is emphasized. Other types of occupational therapy, such as sewing, knitting, and various games, may often offer very satisfactory forms of diversion. In this section Dr. Cabot very ably discusses under the title "The Two Must Face a Third" the minister's relations with the sick, the danger of their dependence on him, and particularly the danger that women patients may fall in love with him. The last is admittedly difficult at times, but Dr. Cabot rejects the necessity of the "transference phenomenon," using the terminology of psychoanalysis, and feels that the situation can usually be avoided by the following precautions: (1) the maintenance of physical distance between the patient and the physician, or minister; (2) the avoidance of touch; (3) the presence of a third person whenever that is possible; and (4) *the implied presence of a third person*, thereby keeping the speech and action at all times entirely as it would be if a third person were present. The discussion of the needs of the

minister is closed with a brief section on the importance of "starting with the patient," taking into account his physical illness, the condition of his mind, his emotions, his spirit, and thereby establishing a satisfactory rapport with him. Good education should likewise start with the student, but Dr. Cabot notes that all too often it does not do so.

The section on methods, written chiefly by Mr. Dick, opens with a chapter on the lost art of listening, for the author feels that "if the Protestant church is to renew its contact and its interest in the care of souls, its leaders must descend from their pulpits and seek out those who are in need. And they must be prepared to listen." The listening must be creative in type, directed, leading the patient to think and talk about a definite subject. In directed listening the Christian minister is thought to make his nearest approach to the Catholic use of the confessional to which, above everything else, in the opinion of the authors, the strength of the Catholic church as an institution is to be attributed. Quietness is described as one of the methods for effective work in the sick room. This quality is desirable for any poised, healthy, happy life; it is peculiarly desirable in illness, but it is difficult to define exactly the technique of its use. In the well-written chapters on prayer and the use of scripture one is strongly reminded of the Gifford Lectures of William James on the "Varieties of Religious Experience." Prayer and the reading of scripture are important for the Christian if the minister is to fully "rouse the great" energies, certainties, and faiths of the Christian religion, but the authors do not recommend their infliction upon the non-Christian unless he so desires. The subject of note-writing is discussed and illustrated in considerable detail. Its importance seems obvious for any minister who takes seriously the task of visiting and aiding the sick. Two chapters by Dr. Cabot conclude the section on methods. The first deals with creative assertion, by which is meant the ability, difficult to define, to recognize heroism; the almost inspired ability to recognize the rare moments when one may, by the positive expression of "admiration, surprise and delight," reinforce or crystallize the patient's courage to the end that we may "build better than we know." The second chapter discusses the rituals of the sickroom, emphasizing the importance of a well-organized routine with one high point or climax daily. The day should be without quarrels or needless disappointments, and there should be moments of affection, or better still, a steady undertone of affection throughout.

The section on critical opportunities is devoted to preparation for an operation, to ministration to the dying, and to consolation of the bereaved. Mr. Dick devotes considerable space to his own experience with operations, because it is illustrative. He feels that the minister can do a great deal to prepare the patient psychologically for the operation, and that the best attitude for the patient to have is, "It is all right whatever happens." The importance of explaining carefully to the patient the result to be expected from the operation is emphasized . The ideal for the patient face to face with death is summed up by the authors in the words of a patient: "It is all right; whether I get well or whether I die—it is all right." Death is considered to be but an incident and the attainment of this point of view the final triumph of religion. The chapter contains a great deal of practical advice and philosophy, all leading to this thought, that "the tragedy or the victory of death is in the way one dies, not the fact of death itself." Dr. Cabot's excellent discussion of bereavement, giving further evidence of his deep insight into human nature, shows clearly that which consoles the bereaved and that which does not.

The appendix contains a number of stories of work with the sick, apparently taken chiefly from the notebook and experience of Mr. Dick. These notes and comments illustrating the importance of keeping a notebook and also many of the points discussed in the book add concreteness and precision to the various topics considered.

There are few who could not read this book with profit, although it probably will not appeal to the enthusiastic atheist, the confirmed sceptic, or the narrow-minded scientist. It should be most helpful to the minister. It should prove very valuable to nurses, social workers, medical students, the younger practitioners of medicine and even to many of those who have spent years in the practice of the healing art. It is a contribution toward the ideal expressed by Francis Peabody in the letter written to his friend and "scientific godfather," Joseph Pratt, at a time when he knew himself to be traveling in the valley of the shadow of death: "My great desire has been to have a medical clinic in which the highest type of scientific work was carried on in conjunction with the most human and sympathetic attitude toward the patients—a type of spiritual atmosphere which may be expressed by the word "Christian."

Walter L. Palmer, Chicago.

EUSTERMAN, GEORGE B.

Diagnostic Aspects of Roentgenologically Negative Gastric Disorders. J. A. M. A., Vol. 107, pp. 1432-1436, Oct. 31, 1936.

The efficiency of modern roentgenologic diagnosis permits classification of diseases of the stomach into roentgenologically positive and roentgenologically negative disorders. In recent years the radiologic diagnosis of gastrointestinal disorders has reached an accuracy of 90 to 95 per cent, although the exact nature of the lesion cannot always be successfully ascertained before microscopic examination. The conditions which are diagnosed by X-ray are gastric and duodenal ulcer, carcinoma, pyloric and duodenal obstruction and duodenal dilatation. It would also include gastritis and granulomatous lesions. Kirklin claims that about five per cent of all ulcers escape detection. The same may be said of small carcinomatous ulcers. Gastritis and small diaphragmatic herniae may also be overlooked at examination.

Gastric disturbances reflexly engend-

ered by disease of the abdominal viscera other than the stomach itself or its continuations exceed in importance the gastric neuroses, because of their nature and extent and the comparative frequency of their occurrence. They constitute from a third to two-fifths of all cases and include disease of the gall bladder, appendix, pancreas, liver, small bowel, colon, and such conditions as epigastric hernia and helminthiasis. The neurosis constitutes about a fourth of the total.

In from fifteen to twenty per cent of cases, gastric disturbances are attributable to disease of organs remote from the stomach, but only on infrequent occasions are such gastric disturbances the sole expression of an extragastric disorder. The most common location of disease in these cases is in the circulatory, pulmonary, nervous or urinary systems. Next in importance are diseases of dysfunction of the endocrine organs, deficiency diseases, toxic states induced by noxious gases, heavy metals, drugs, and inordinate use of tobacco and alcohol.

Complete and careful physical examination and a few well chosen laboratory tests will usually disclose the true nature of the condition.

McCOY, GEORGE W., AND HARDY, ALBERT V.

The Clinical Diagnosis of Amebic Dysentery. J. A. M. A., Vol. 107, p. 1357, Oct. 24, 1936.

The diagnosis of amebic dysentery is the most important point in handling the disease. Specific medication brings prompt and immediate relief, while symptomatic medication prolongs the condition and is hazardous to life.

Amebic dysentery must be considered an endemic disease which shows no predilection for any one area or any one class. Its incubation period varies from a few days to three months, but usually is one to three weeks. It must be considered in the differential diagnosis in all cases of enteric infection.

Clinically the disease usually is characterized by gastro-intestinal symptoms, but in some instances the invasion may be so mild that the entire picture is veiled. The more severe manifestations include evidences of an acute or chronic ulcerative process in the large bowel.

The onset of the disease varies. In 18 per cent of the 1,215 cases here reported, the onset was abrupt with symptoms other than diarrhea or abdominal pain. Fever and vomiting with abdominal pain localized in the right lower quadrant, and accompanied by tenderness and rigidity often served to limit attention to the appendix. Appendectomy in these cases resulted in death in 41 per cent of thirty-two cases. Rectal distress with bloody stools resulted in the diagnosis of hemorrhoids. Other cases were diagnosed malignancy because of the weakness, mild diarrhea and blood in the stools with a mass in the region of the cecum or colon on examination. Fever was found to be present in seventy per cent of the severer infections.

The errors in diagnosis were usually the acceptance of a nonetiologic diagnosis such as colitis or "dysentery." In fatal cases the erroneous diagnoses in order of frequency were malignancy, appendicitis, appendiceal abscess, sepsis in or near the gall bladder and in one case, hemorrhoids.

In the total series of 1,409 Chicago cases there were 98 deaths. The highest fatality rate being in the nonhotel cases which had progressed for months or years. In no instance is it known that a fatality resulted where an early diagnosis was made and specific therapy was used.

The diagnosis of amebic dysentery depends upon a more persistent effort to arrive at an etiological diagnosis of all diarrheal diseases, and the recognition of the fact that it is widespread in the United States and that its clinical manifestations vary widely.

KIRK, ROBERT C.

The Takata-Ara Test and Its Relation to Cirrhosis of the Liver. J. A. M. A., Vol. 107, pp. 1354-1357, Oct. 24, 1936.

Clinicians everywhere are anxious for a liver function test which is of definite diagnostic value. Because of this, this investigation of the Takata-Ara test was carried out.

This reaction was originally used by Takata to differentiate lobar from broncho-pneumonia. It is based upon the fact that when fluid from the chest of a patient with lobar pneumonia is added to a solution of sodium carbonate, mercury bichloride and acid fushsin, a precipitate of mercury oxysol occurs. This is believed to be due to a decreased stability of the serum proteins produced by an increase in the globulin fraction. Later Takata and Ara used it in differentiating syphilitic and miningitic central nervous system disease.

Jeyler recognized the fact that a protein shift in the blood was not peculiar to lobar pneumonia, but also was present in liver disease. He found that the test was positive in all advanced cases of cirrhosis and usually negative in all other diseases.

The method used was as follows: to a nine-tenths per cent solution of sodium chloride the patient's serum was added and many dilutions made, varying from 1:2 to 1:61. To these dilutions 0.25 c.c. of a ten per cent solution of sodium carbonate was added, followed by 0.15 c.c. of a five-tenths per cent mercury bichloride. The tubes were shaken and read in five minutes and again in twenty-four hours. A pearly flacculent precipitate filling at least one-fourth of any tube and a definite precipitate in any of the first four tubes was considered positive, all others negative.

Of 106 patients on whom the test was used, the following results were obtained. Cirrhosis of liver, 15 were positive and 6 were negative. Five of the fifteen positives were confirmed at autopsy. Congestive heart failure, 7 were positive and 7 were negative, four of each showing the presence or absence of liver damage at autopsy. Hepatitis, 2 were positive and 3 were negative; cholecystitis, 3 were negative; liver malignancy, 3 were positive and 2 were negative; abscess of liver, one was negative; congenital hemolytic jaundice, 2 were positive and 2 were negative; leukemia, one was positive and one was negative; tuberculosis, two were positive and two were negative; lobar pneumonia, one was positive and four negative; hyperthyroidism, four were negative; and normal livers showed 6 positive and 32 negative reactions.

The rationale of the test is not well understood, but the author comes to the conclusion that it is not diagnostic of cirrhosis of the liver, and that any disease which causes an elevation of the globulin level is likely to produce a positive reaction.

GOLDMAN, LEON.

Gross Hemorrhage from Peptic Ulcer. J. A. M. A., 107:1537, November 7, 1936.

Many physicians do not appreciate the potential dangers of bleeding from a peptic ulcer. Of 349 patients entering the San Francisco Hospital because of gross hemorrhage, 15 per cent died from hemorrhage or associated conditions: perforation of the ulcer, pneumonia, cerebral or cardiac thrombosis.

Ulcers of the stomach heal more readily than those of the duodenum, which bleed more readily. Fatal hemorrhage is usually caused by erosion of a large artery. Arteriosclerosis is an important influence on the incidence and mortality.

Recurrence of ulcer symptoms precedes hemorrhage. Nausea, vomiting of blood, tarry stools, fainting and shock occur. The blood pressure is an early guide to the severity of the hemorrhage. The patient's age and the presence of arteriosclerosis are important prognostic factors. The mortality has been reported high—from 14.5 per cent to 58 per cent.

In this study the mortality rate of patients with ulcer was 17 per cent, in-

creasing in direct proportion with the age of the patient. The average age of the patients who died was 54, and the greatest incidence was between 40 and 70. 70.6 per cent showed evidences of arteriosclerosis. There was an abrupt rise in mortality after the second hemorrhage, showing that the ulcer was intractable to medical treatment and that surgery was indicated.

The plan of treatment was as follows: (1) absolute rest, (2) morphine to insure mental and physical rest, (3) frequent determination of blood pressure, hemoglobin, and red blood cells, (4) nothing by mouth except alkaline powders, (5) no intravenous fluid except blood for several days, (6) blood transfusions, (7) coagulants and astringents have little effect, (8) gastric lavage only if there is an accumulation of blood clots. If the patient fails to respond to medical treatment early surgery is indicated.

EUSTERMAN, GEORGE B.

Diagnostic Aspects of Roentgenologically Negative Gastric Disorders. J. A. M. A., 107:1432, Oct. 31, 1936.

A negative roentgenologic report of the digestive tract, if skillfully done, eliminates ulcer of the stomach and duodenum, gastric carcinoma, pyloric and duodenal obstruction, duodenal lesions, and deformities caused by adhesions. These roentgenologically positive disorders cause about 1/5 of the cases of chronic dyspepsia at the Mayo Clinic. The roentgenologically negative diseases are classified as follows:

(1) Unrecognized roentgenologically positive gastric disorders. Gastric and duodenal ulcers and small carcinomatous ulcers may easily escape detection or be impossible to detect. Gastritis and diaphragmatic hernias are also very easy to miss in examination.

(2) Roentgenologically negative disorders of the stomach itself. This group includes the functional disturbances or neuroses, habit dyspepsias, constitutional inadequacy, some forms of gastritis, and gastric allergy. Neuroses are the most common, accounting for ¾ of the "stomach trouble" at the clinic. Some features which characterize gastric neuroses are: (1) long duration without complications, (2) symptoms variable in degree and location and frequently continuous, (3) lack of sequence characteristic of organic lesions, (4) diffuse pain, (5) symptoms lacking at night, (6) disorders following emotional stress, (7) physical disability out of proportion to the severity of the complaint, (8) other evidence of psychoneurosis or hysteria. A personal or family history of asthma, hay fever, uticaria or eczema makes allergic disease a possibility. The disturbance here is a spasm of the smooth musculature.

(3) Gastric disturbances resulting from disease of the abdominal viscera other than the stomach itself. 1/3 to 2/5 of the gastric disorders have their origin in the gall bladder, appendix, pancreas, liver, small bowel, colon, or such conditions as epigastric hernia or helminthiasis. Cholecystitis is the most common. Diseased appendix is not as important as formerly considered. Liver disease is diagnosed by icterus or anasarca or by hepatic function tests and roentgenographic examination of the esophagus. The pain due to pancreatitis is very hard to diagnose and distinguish from perforating ulcer, cholecystitis, diaphragmatic hernia, renal and colonic lesions, sciatica and lumbago, but increased activity of serum lipase is an efficient test for pancreatitis. Intestinal disorders must be diagnosed by inquiries into the past history if the pain is at the umbilical level or lower. Addison's

Smooth Laxation

NATURAL MOVEMENT -- NO LEAKAGE

(The Alkaline Mineral Oil Laxative)

The administration of Genuine Phillips' Milk of Magnesia and pure mineral oil in this creamy, palatable homogeneous emulsion supplies the need for a satisfactory method of correcting constipation and hyperacidity.

Usual Dose: 1 to 2 tablespoonfuls before breakfast and at bedtime.

Supplied in 8-oz., 16-oz., and 32-oz. bottles.

Samples to Physicians on Request.

170 Varick Street New York, N. Y.

disease, intestinal parasites, tuberculous peritonitis, retroperitoneal adenopathy, and disease of the lower thoracic vertebrae must also be excluded

(4) Gastric disturbances resulting from disease remote from the abdominal organs Disease of the circulatory, pulmonary, nervous, or urinary systems may give rise to gastric symptoms and must be carefully considered. Endocrine dysfunction, deficiency diseases (such as pernicious anemia) and toxic states are often important factors. Gastric disturbances are seldom the only manifestations of these disorders and careful laboratory investigation will usually reveal the true nature of the underlying cause.

Francis D. Murphy, Milwaukee.

JORDAN, SARA M.

A Review of the Gastric Ulcer Problem. J. A. M. A., 107:1451, Oct. 31, 1936.

119 cases in which a diagnosis of gastric ulcer was made on a reasonable basis were studied. The following questions arise in the treatment of gastric ulcer:

(1) Is the visualized lesion actually organic? Spasm, adhesions, cicatrization of an old lesion, and a loop of small intestine may be confusing since they may deform the contour of the stomach. Exploratory laparatomy is sometimes necessary to make the correct diagnosis but usually repeated fluoroscopic examinations with spot films and trial observations and treatment checked by radiological examinations are sufficient.

(2) Is it benign or malignant? The history is often not reliable. If the duration has been short and the symptoms not compatible with those of ulcer, malignancy is probable. A recent change in symptoms, absence of food relief, and frequency of vomiting and loss of appetite and weight without obstruction indicate malignancy. Analysis of the gastric contents is important because there is usually free hydrochloric acid with an ulcer and achlorhydria with cancer. Occult blood in the stools points toward carcinoma, but this test must be made carefully and over a long period of time. A healed lesion is not malignant. Prepyloric and posterior wall lesions heal slowly and tend to become malignant. In any doubtful case trial treatment should be given to determine reaction and a careful follow-up made.

(3) Is it healable by medical treatment or would surgical treatment be a more adequate insurance against recurrence or malignant degeneration? Operation should be done if there is suspected malignancy or if recurrence might lead to future malignancy. Uncontrollable distress is a surgical indication, but this rarely occurs except in a posterior wall lesion penetrating the pancreas. Surgical treatment is considered greater security against malignancy, but adequate follow-up evidence is not yet available.

(4) Is it necessary to guard against recurrence of the gastric ulcer as if it were distal to the pyloric sphincter? If patients who have had a gastric ulcer continue to live an "ulcer life" they are less prone to recurrences than those who consider themselves ulcer-proof. It is necessary to eat carefully, abstain from smoking or drinking and avoid fatigue and worry.

BOLES, RUSSELL S., AND CLARK, JEFFERSON H.

The Role of Alcohol in Cirrhosis of the Liver. J. A. M. A., Vol. 107, pp. 1200-1203, Oct. 10, 1936.

Cirrhosis of the liver is a fairly common chronic disease, presenting in its later stages a well recognized clinical and pathologic picture. In its early stages the clinical diagnosis is seldom evident and is based more on presumption than on fact.

The etiology of the condition is not known, but is believed to be due to

℞ TAUROCOL

A Free Flow of Bile . . .

is essential in the correction of constipation and hepatic insufficiency. TAUROCOL BILE SALTS TABLETS stimulate the flow of bile and are recommended by leading physicians for the treatment of early cirrhosis, and catarrhal and other forms of jaundice; or what is more common, chronic constipation which is, in the main, due to hepatic insufficiency.

Other Plessner Products

A. J. D. 2-37

various toxic agents, which cause a destruction of liver cells and a proliferation of connective tissue with ultimate fibrosis of the organ. Alcohol has for many years been considered the etiologic agent together with such conditions as syphilis, tuberculosis, diabetes, and acute infections.

Lately the status of alcohol as the etiologic agent has been disputed. Because of this, 4000 autopsies were studied from March, 1933 to1935, with especial reference to histologic evidence of cirrhosis in these cases, and the age, sex and race of the individuals. The relationship which alcohol, acute infections, syphilis, diabetes and tuberculosis bore to the disease was also studied.

Following their observations the authors present the following classifications as more accurate and descriptive:

1. Circulatory—occurring in cases of prolonged circulatory failure incident to advanced myocardial degeneration with red atrophy of the liver.
2. Degenerative—occurring as a result of degeneration and necrosis of liver cells and proliferation of fibrous tissue and bile ducts. This type is believed to be due to alcohol and other toxic agents.
3. Infectious—a low grade infection producing fibrous tissue in the periportal spaces.
4. Obstructive—believed to be due to an obstruction of the bile flow with increased fibrous tissue and bile duct proliferation.
5. Pigment—the deposition of abnormal pigment resulting in a histologic picture similar to the obstructive type.

The cases were grouped as follows: 1. All those regardless of history that presented definite or questionable histologic evidence of cirrhosis. 2. All cases in which the clinical history stated that the patient was addicted to alcohol. 3. Cases in which the liver weighed more than 2000 grams except in conditions not related to this study.

In the first group there were 243 cases or six per cent. Most of these were males, and only 84 or 35 per cent gave a history of alcoholism. Of all these cases only two were observed in children. Of this group 62 per cent were of the portal type and 70 per cent of these did not present any history of alcoholism; 34 cases were of the fatty type and 80 per cent of these had an alcoholic history; 33 cases were of the cardiac type of cirrhosis and 85 per cent of these were nonalcoholic; 18 cases of the infectious type with no alcoholic history; 8 cases of biliary cirrhosis of which 50 per cent were alcoholics. In all the cases no case of pigment cirrhosis was observed.

The 4000 cases were further studied to determine how many with an alcoholic history showed definite evidence of cirrhosis. Of 228 cases with an alcoholic history 24 per cent showed definite cirrhosis and 13 per cent showed fatty metamorphosis.

Of those cases in which the liver weighed over 2000 grams there were 151, seventy-five of which were alcoholic and seventy-six nonalcoholic. Of the alcoholic, 40 per cent had portal cirrhosis and eight cases showed fatty degeneration. Of the nonalcoholic, 39 per cent had portal cirrhosis and six cases showed fatty degeneration.

Concerning other etiological factors, 31 per cent gave a history of acute infections; 9 per cent had active pulmonary tuberculosis, 11 per cent had syphilis and diabetes was present in thirteen of the cases.

The above results indicate that cirrhosis is not caused by any one of the indicated agents. The author further believes that the term alcoholic cirrhosis be abandoned because the lesion occurs under a variety of conditions.

Francis D. Murphy, Milwaukee.

"The Food Canal is a Soft Tube with a Hard Life"

—MONTAGUE

● Numerous authorities in the field of gastro-enterology regard the intestinal tract as the most important source of systemic infection in the entire body.

The administration of Soricin in sufficiently large doses has been shown by Burger and Dorst to detoxify intestinal organisms and their filtrates.

More recently Myers, MacQuiddy and Hamer have demonstrated that Soricin inhibits the action of the proteolytic and putrefactive bacteria upon the contents of the bowel.

Soricin has pronounced detoxifying properties without destructive effect on tissues with which it comes in contact. For this reason Soricin is both effective and safe—even in liberal doses.

Soricin-Merrell

DOSAGE FORMS: Soricin Capsules—Enteric capsules of sodium ricinoleate available in five-grain and ten-grain sizes. Soricin Tablets—Enteric coated tablets each containing five grains of sodium ricinoleate.

ACTION: Detoxifies in vivo • Desensitizes • Inhibits putrefaction • Prevents toxic absorption.

INDICATIONS: Bacterial Hypersensitivity of the intestinal tract • Intestinal toxemia • Intestinal allergy • Allergic diarrhea • Urticaria • Angioneurotic edema • Colitis.

WHITE, C. S., AND COLLINS, J. L.

Acute Mesenteric Adenitis. J. A. M. A., Vol. 107, pp. 1023-1025, Sept. 26, 1936.

Acute mesenteric adenitis has not been recognized by many as a distinct medical or surgical entity. The author has had sixteen cases during the years 1931 and 1935 which presented a history and symptomatology resembling that of appendicitis. At operation none of these cases presented the pathological findings of acute appendicitis. The outstanding pathological finding was an enlargement of the glands in the distal three feet of the mesentery of the small intestine, together with a small amount of peritoneal exudate and a moderate congestion of the cecum and small intestine.

The condition is characterized clinically by an onset of abdominal pain without previous history of any infection. This pain is generalized but more intense in the lower abdomen. The temperature is usually about 102 to 103 degrees Fahrenheit with pulse and respirations corresponding. Constipation is usually present, together with nausea, but vomiting only until the contents of the stomach are emptied.

Physical examination reveals a moderately distended abdomen with tenderness in the lower abdomen. The white count usually is between 8,000 and 14,000.

The etiology of the condition is not known, some men believing it to be tuberculous in nature and others that it is due to some intestinal disorder. The author suggests the possibility that it may be due to a virus, such as is believed to cause poliomyelitis or influenza. Sometimes the differential diagnosis between this condition and genuine acute appendicitis is very difficult or impossible. The higher fever, the general malaise before onset of pain as seen in the cases of adenitis at times may be helpful.

Francis D. Murphy, Milwaukee.

TAYLOR, FREDERICK.

"The Acute Gall Bladder." S. G. O., 63:298-307, Sept., 1936.

This comprehensive and convincing article offers further argument for the increasingly popular prompt surgical treatment of acute gall bladder disease. The classification of the cases into acute edematous, acute suppurative, and acute gangrenous, is entirely a pathological one. In considering the usual signs and symptoms, such a differentiation, clinically, is impractical, the most outstanding variance being seen in the total white count which averaged, respectively, 12,500, 15,200 and 20,000, with some definite overlapping. The underlying lesion in the acute gall bladder is a vascular one upon which an inflammatory or infectious process may be superimposed. The usual symptoms are discussed and the observations made that all the signs and symptoms need not be present to make the clinical diagnosis of an acute gall bladder.

The mortality analysis of operated cases is of greatest interest and importance. Patients operated upon within 48 hours and those two to five days after the acute onset showed approximately the same mortality, five per cent. Those operated upon five days or more after the acute onset showed a mortality of twenty-three per cent. When it is realized that these time intervals apply to the date of onset and not to the date of admission to the hospital, it will be seen that rather prompt surgical treatment is usually indicated. In all instances, however, time must be allowed for the preoperative intravenous glucose and fluid administration. Since over 90 per cent of the cases coming to operation show

Adequate Treatment of Pernicious Anemia

● Of paramount importance in the treatment of pernicious anemia is the administration of adequate antianemic material, such as is contained in liver, to restore hemoglobin and red blood cell levels.

In cases where there is evidence that subacute combined degeneration of the spinal cord is present, therapy must be adequate to arrest completely all progress of the cord degeneration.

Adequate doses of solutions of liver extract can be conveniently given by parenteral injection. For this purpose the following preparations are offered:

Solution Liver Extract Concentrated, Lilly—Supplied in 10-cc. rubber-stoppered ampoules and in packages of four 3-cc. rubber-stoppered ampoules.

Solution Liver Extract, Lilly—Supplied in 10-cc. rubber-stoppered ampoules.

stones in either the gall bladder or cystic duct, and since the majority of the patients have had previous symptoms, operation is, of course, the indicated treatment. The burden of proof rests upon those who advocate waiting for the acutely inflamed viscus to "cool"—during which time gangrene, perforation, extracholecystic abscesses or peritonitis may occur and the mortality rate greatly increase.

EXPERIMENTAL PHYSIOLOGY

McGOVERN, F. H.

Primary Tularemic Ulcers in the Pharynx. J. A. M. A., 107:1629, Nov. 14, 1936.

The author presents the case of a woman, aged 32, married, who entered the hospital because of an extreme sore throat of twelve days duration. The onset had been sudden with chills and fever. It was later learned that she had picked ticks from her pet dog one week previous to the onset of the disease. Physical examination revealed a large confluent ulceration of the posterior wall of the pharynx. The cervical glands were bilaterally large and tender. The temperature was 102.4° F. on admission. The urine was normal. The white blood cell count was 21,000 with a marked shift to the left. Cultures were negative for diphtheria. A diagnosis of Vincent's angina was made and treated with arsphenamines and antimony and potassium tartrate with no results. The throat was sprayed with one per cent mercurochrome with marked relief of the symptoms. Because of the unusual course of the case agglutinations for typhoid tularemia, typhus, and undulant fever were done. The first report showed a four plus agglutination against Brucella abortus in a dilution 1:320 and two plus in 1:1280. A one plus agglutination was found against the B. tularense in a dilution of 1:640. Six days later the B. tularense agglutination was four plus in a dilution of 1:1280 and the Brucella abortus agglutination was three plus in a 1:20 dilution. The U.S.P.H.S. found an agglutination for B. tularense in dilution of 1:2560 and 1:5120. The patient was afibrile two days after admission and was discharged six days later. Two months later she was in excellent health.

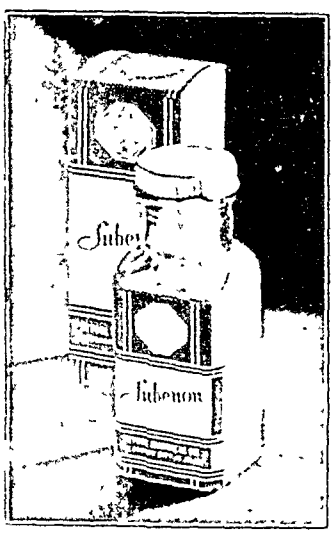
GOLDMAN, L.

Gross Hemorrhage from Peptic Ulcer. J. A. M. A., 107:1537, Nov. 7, 1936.

Hemorrhage from peptic ulcer is considered by many physicians to be a comparatively rare cause of death. The record of pathologists, corners, and large city hospitals, however, do not confirm this idea.

At the San Francisco Hospital, of the 1,025 entries of 890 patients with peptic ulcer 348 or 38 per cent entered because of gross hemorrhage from a peptic ulcer. Of these 11.1 per cent died of exsanguination, while an additional 4.9 per cent died of conditions associated with the bleeding.



An ulcer which causes gross hemorrhage is necessarily active and progressive. If it is in the posterior wall of the duodenum and invades the retroduodenal and pancreatic tissue an inflammatory process is set up with the formation of adhesions which hold the ulcer open. The vessel most frequently involved in fatal cases is the superior pancreaticoduodenal or one of the coronary vessels of the lesser curvature of the stomach.

The symptom may appear suddenly in a patient with or without an ulcer history. The first symptom usually is nausea, followed by vomiting of blood.

When Acidosis Complicates Disease

Supporting the alkali reserve has become a routine measure in diseases characterized by acidosis. For this purpose, Alka-Zane is extensively used because it supplies the four bases of which the reserve is essentially composed: sodium, potassium, calcium, magnesium. These are made available to the organism in the form of carbonates, citrates and phosphates. Alka-Zane contains no tartrates, lactates, or sulphates, and no sodium chloride. It is a convenient and efficient way to prescribe alkalizing medication that is palatable and easy to take.

Alka-Zane is supplied in 1½, 4 and 8 ounce bottles. Trial supply sent on request.

ALKA-ZANE

The stools may or may not be tarry. This may be followed by shock if the hemorrhage is severe enough.

The percentage of cases of peptic ulcer which develop hemorrhage varies greatly. Various clinics find that from 19 to 31 per cent of the hospital cases develop hemorrhage and 10 per cent if outpatients are included.

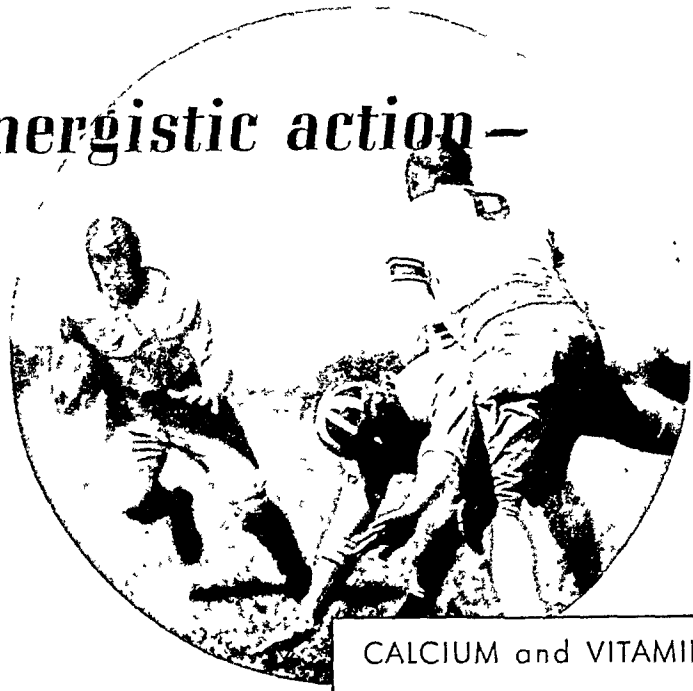
The mortality also varies in different clinics being between 14.5 and 58 per cent. At the San Francisco Hospital the mortality, when complications of hemorrhage are included is 15 per cent. Two of the patients included in this series developed perforation after the hemorrhage. Most of these cases with hemorrhage were between 40 and 70 years, the average age being 54 years.

The successful treatment depends upon bed rest, sedation with morphine if necessary, blood transfusion and the withholding of food. Parenteral fluids should be withheld for the first 24 to 48 hours. Gastric lavage should be reserved from those patients in whom the stomach is distended by blood clots.

Those cases who continue to have severe hemorrhage or repeated hemorrhage require surgical intervention because a large vessel usually is eroded. The type of operation to be performed depends upon the operative findings. The vessels are usually ligated and in some cases an anastomosis is made between the stomach and the jejunum.

F. D. Murphy, Milwaukee.

FAULEY, G. B., AND IVY, A. C.



"The Prevention of Postoperative Jejunal Ulcers by Diet and Fundusectomy: An Experimental Study in Dogs." S. G. O., 63:717-724, Dec., 1936.

This work, all experimental on dogs, offers some conclusions that may prove to be of great clinical importance. The Mann-Williamson operation (gastrojejunostomy and drainage of bile and pancreatic juice into the last 15 centimeters of the ileum) invariably produces experimental ulcers analogous etiologically to postoperative jejunal ulcers in man.

When this operation was followed by the regular stock diet all the dogs died of ulcer within 17 weeks. If instead of the regular stock diet a special diet high in nuclear substances, vitamins and readily assimilable carbohydrates was used there was a marked delay in the development of the ulcer and the onset of fatal hemorrhage and perforation. However the dogs living longer than 20 weeks showed an ulcer incidence of 90 per cent.

Although the authors were convinced that fundusectomy does not produce a permanent lowering of the gastric acidity the two experiments just described were tried again on dogs which had been fundusectomized several weeks before a Mann-Wil-

Synergistic action—

CALCIUM and VITAMIN C are the main ingredients of **CAL-C-MALT 'ROCHE'**

- SOUND TEETH
- IMPROVED APPETITE
- ROBUST HEALTH

Frequently prescribed in cases in which the vitamin-C reserve needs building up to resist infection. Each dose contains 50 mg of vitamin C 'Roche', as much of this vitamin as is contained in two average size oranges.

Cal-C-Malt, moreover, is an effective nutritive tonic, increasing appetite and facilitating a much-needed gain in weight in run-down patients.

MIX CAL-C-MALT WITH MILK

IT MAKES A DELICIOUS, HEALTHFUL DRINK

In addition to dicalcium phosphate and vitamin C, Cal-C-Malt contains vitamin B (the appetite vitamin) and diastatic malt, all combined in the finest quality chocolate base.

liamson operation was done. Ulcer formation was observed in only three of eleven animals where there was fundusectomy, Mann-Williamson operation and regular stock diet. Of the thirteen animals having fundusectomy, Mann-Williamson operation and special diet none developed an ulcer although six lived longer than two years.

While there was not a great decrease in the total amount of acid in fundusectomized dogs one very interesting finding was observed. The average amount of gastric content at the end of four hours was only 40 per cent of that present in dogs where fundusectomy had not been done—in other words, the acid available for prolonged irritation of the jejunum was definitely less. This explanation may be of considerable significance.

J. Duffy Hancock, Louisville.

MONTGOMERY, M. F., AND STUART, J. S.
Studies on Secretion of Oral and Pharyngeal Mucous. Amer. Jour. Phys., 115, No. 3, May, 1936.

Studies were made on oral mucous and pharyngeal glands in regard to response to various stimuli, reflex response, and reaction to drugs; as compared to the salivary glands. Secretory response was estimated by direct observation of the glands and by collection of oral and pharyngeal secretion after eliminating the salivary supply, by means of esophageal fistulae. The mucous glands were observed to respond to nerve and drug stimulation in the same manner as the salivary glands. They do not secrete continuously, but only in response to conditioned and unconditioned reflexes. The mucous gland appear more responsive to mechanical stimulae than salivary glands. With exception of acid the mucous glands have a lower threshold of stimulation to taste and olfactory stimulae than the salivary glands. The mucous glands are less effected by water deprivation than the salivary glands as regards secretory rate.

NUTRITION

SVIRBLEY, J. L.
The Effect of Diets and Various Substances on the Vitamin C Content of Some Organs of the Rat. Amer. Jour. Phys., 116, No. 2, 446-455.

Experimental study on rats was undertaken to obtain further data on the site of synthesis in the body of ascorbic acid and on the nature of its precursors. Rats were placed on various diets and after periods of time sacrificed and the organs analized for ascorbic acid by titration with indophenol indicator. The author found that under all conditions of diet the rats were able to synthesize their own vitamin C, however on vitamin B free diet the content of the organs in ascorbic acid was markedly reduced. Of the organs capable of synthesizing ascorbic acid only the liver and gut need be considered, their relative ability to form ascorbic acid apparently depending to some extent on the precursor in the diet, as shown by the relative concentrations of this vitamin in the organs. The vitamin C content of organs is decreased by nitrophenol, desiccated thyroid, and sodium fluoride and thyroid gland simultaneously administered in subminimal dosages. Vitamin C content of the liver is lowered by cincophen or ether administration. That the gut is the site of formation of ascorbic acid is suggested by the author because that substance is still synthesized in appreciable amounts after degenerative changes, and presumably disarrangement of hepatic function has been brought about by exposure to carbontetrachloride vapor.

I. S. Cherry, Chicago.

CLARKE, M. F., BASSIN, A. L., AND SMITH, A. H.
Skeletal Changes Due to Low Inorganic Salt Diet. Amer. Jour. Phys., 115, No. 3, 556-563, May, 1936.

Studies on bone of rats fed on low salt diets for various periods were undertaken to show relative variations in ash and fat free organic residues, moisture content and dimensions, between these and control rats qualifying in age, weight and caloric intake; and to correlate these if possible with breaking strength of the bone. Studies were continued further to determine if, on the exhibition of salt in the diet the bones of the deficient animals could approximate that of the controls. In these animals it was found that body weight ceased, but the long bones continued to increase slowly in length. The ash decreased and the moisture content of the bone increased during the salt free period. The proportion between ash and fat and moisture free organic residue became markedly distorted from that of the controls. Recovery on resuming salt was noted, but the percentage of moisture and ash as well as measurements failed to reach the age control values. Breaking strength appeared to depend more on structure as reflected in the size, rather than on the relative mineral content.

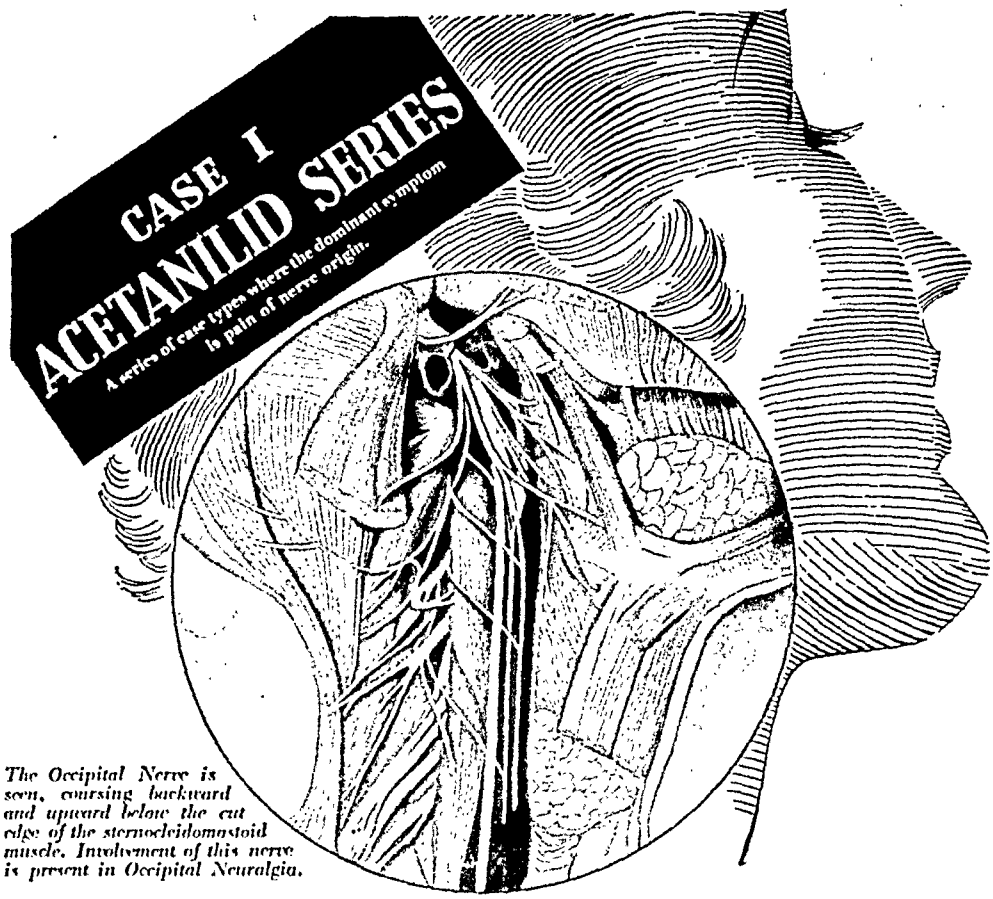
THERAPEUTICS



EADS, JOHN T.
The Use of Histidine Hydrochloride (Larostidin) in the Treatment of Peptic Ulcer. Ann. Int. Med., X, pp. 638-644, Nov., 1936.

This report deals with 85 cases of peptic ulcer (77 duodenal and 8 gastric ulcer) which have been treated with

CASE I

ACETANILID SERIES

A series of case types where the dominant symptom is pain of nerve origin.

The Occipital Nerve is seen, coursing backward and upward below the cut edge of the sternocleidomastoid muscle. Involvement of this nerve is present in Occipital Neuralgia.

OCCIPITAL NEURALGIA

CHIEF COMPLAINT: Paroxysmal pain with free intervals; tenderness of neck toward right ear.

HISTORY: Frequent colds; lack of energy; appetite poor; sleeplessness, and irritability.

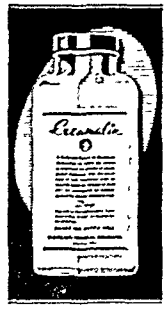
PHYSICAL: Underweight; anemic; neurasthenic type.

SYMPTOMS: Hyperesthesia right cervical area midway between occiput and mastoid process.

DIAGNOSIS: Occipital neuralgia caused by exposure or infection.

TREATMENT: (Symptomatic) Acetanilid, 2-5 grains q. 4 hrs.

Bromo-Seltzer provides 3 to 3.5 grains of Acetanilid, plus its synergists—*Caffeine and Bromides—in each teaspoonful dose. Caffeine gently invigorates* the mental processes. Bromides promote relaxation of overwrought nerves. Citrates improve digestion, tend to replenish alkaline reserve and give to Bromo-Seltzer its effervescent palatability.



Bromo-Seltzer relieves pain effectively and economically.

Requests for sample and literature receive prompt consideration.

EMERSON DRUG COMPANY · Baltimore, Md.

Rapid Control of Pain

with

Creamalin

The Specially Prepared Colloidal Cream of Aluminum Hydroxide for

PEPTIC ULCER

"Pain disappeared after the first dose" is the significant comment of many clinicians in reporting their experiences with Creamalin therapy.

The ability of Creamalin to control pain and pylorospasm speedily is undoubtedly due to its unique astringent properties as well as to its rapid acid-fixing action. The special process employed in the preparation of Creamalin may well account for its unusual analgesic action. Try Creamalin and observe its rapid effect on pain.

The Creamalin Continuous Drip Treatment. Although Creamalin has yielded gratifying results in thousands of cases of peptic ulcer when administered orally, certain types of cases are more amenable to a form of treatment whereby diluted Creamalin is administered as a continuous drip. These cases include those 1) wherever a high nocturnal acidity renders the case refractory to intermittent oral treatment; 2) bleeding ulcers; 3) the generally refractory type. In one institution alone, 142 cases have been treated by the Creamalin Drip, and with one exception, x-ray findings were negative in from seven to ten days.

The Creamalin Automatic Drip Control, designed to simplify and facilitate the technique of continuous drip administration, now makes the whole therapy a simple routine. Write for information and for material for clinical evaluation.

CLEVELAND CHEMICAL ASSOCIATES

3616 Euclid Avenue

Cleveland, Ohio

daily intra-muscular injections of a 4 per cent solution of histidine hydrochloride. The number of injections varied from 15 to 36 with 70 cases receiving 24 injections each. These cases were followed up for periods ranging between six and eighteen months.

In the majority of the cases in which clinical improvement was manifest, it occurred early in the course of treatment, usually before five injections had been given; the poorest response occurred in those having 24 or more injections. A gain in weight, appetite, and sense of well-being accompanied clinical improvement but this tended to drop off during the follow-up period.

Patients presenting evidence of obstruction were not benefitted. Gastric ulcer patients yielded the best results both clinically and roentgenologically. Eight cases previously operated upon showed the quickest clinical improvement and five of these remained well after one year's observation. Likewise, those patients in the younger group, with shorter histories and no complicating factors such as obstruction or hemorrhage appeared to respond more quickly and more completely to the treatment.

Regarding the immediate results of histidine Eads could note no untoward reactions in any cases. Temperature, pulse, blood pressure and blood counts were unaffected. But only eight patients showed appreciable lessening in gastric acidity.

Eads concludes that the follow-up periods of from six months to 18 months in his 85 cases have shown that the favorable results obtained immediately during the active course of treatment with histidine hydrochloride are not continued in from 35 per cent to 65 per cent of his two groups of cases. His review of the literature in general supports this conclusion. For the average peptic ulcer patient Eads believes that the use of histidine alone offers less lasting beneficial end-results than does the regular orthodox medical treatment but that it might be worth trying in patients refractory to other regimens. The promptness with which subjective symptoms of pain and discomfort were allayed was noteworthy despite the failure to secure permanent relief. The mechanism by which histidine therapy produces benefit in those cases showing immediate improvement is, in Eads' judgment, by no means satisfactorily explained.

From a study of his own cases as well as from his review of the literature, Eads believes that histidine hydrochloride therapy cannot supplant the dietary-alkaline medical treatment.

C. F. Wirts, Jr., Philadelphia.

ABDOMINAL SURGERY

SHIER, R. V. B.

Large Bowel Obstruction. S. G. O., Vol. 63, No. 4, Oct., 1936.

Carcinoma of the large intestine, volvulus of the cecum or sigmoid, diverticulitis, and congenital or operative adhesions are the etiologic agents of large bowel obstruction. Stone in the kidney frequently produces symptoms simulating large bowel obstruction. The author bemoans the fact that only 15 per cent of the patients with large bowel obstruction consult a physician before it has advanced to a marked degree. A plea is made to treat the dehydrated, chronically poisoned patient, whose cellular structure is altered chemically and physiologically, before attacking the carcinoma. Treat the obstruction first, then the carcinoma.

To relieve the obstruction a cecostomy at a point removed from the ileocecal valve is made through a McBurney incision. After the bowel has been opened irrigations per rectum are started, and usually after 2-3 days through and through washings are made. The patient is fed and the toxic state corrected in from 10 to 14 days, after which the attack on the carcinoma may be made. The author prefers to have the patient out of bed for a few days before attempting the next stage.

If the hemoglobin is below 65 per cent a transfusion is given the night before, or immediately before the operation. An operative procedure adaptable to the particular growth found is made, and after two weeks the patients are allowed to get out of bed. Two months elapse before the cecostomy is closed.

The author feels that our next step forward in increasing the curability of carcinoma of the colon lies in getting the patients before the onset of partial obstruction.

Nelson Percy, Chicago.

HARKINS, HENRY N., HARMON, PAUL H., AND HUDSON, JEANNE E.

Peritonitis Due to Bile and to Liver Autolysis. J. A. M. A., Vol. 107, pp. 948-953, Sept. 19, 1936.

Bile peritonitis is a distinct clinical entity that is probably more common than has been realized. The etiology of this condition is not known, but has been supposed to be due to toxic action and anaerobic growth. The author in this instance wishes to advance the idea that secondary shock due to a decrease in the volume of the circulating fluid is an important lethal factor in this condition.

Peritonitis was produced in dogs by the intraperitoneal injection of ten per cent bile salt solution or whole gall bladder bile. This was followed by a gradual but profound lowering of blood

Gastric Ulcers Heal More Quickly...

and recurrences are less frequent when Irradiated Pet Milk is used in the diet.

The reasons — Pet milk is more easily digested than ordinary milk — less likely to cause intestinal irritation, and consequently conducive to early healing of affected areas.

It is sterile — completely and *surely* free from bacterial life — a positive safeguard against re-infection of healing tissues by milk.

Further recommending it strongly for use in cases of gastro-intestinal disorders are these additional qualities:

1. Uniformly rich in calories, furnishing twice the food value of ordinary milk.
2. Better balanced in nutritional elements than the usual milk and cream mixture.
3. Contains whey proteins so altered in character that they do not readily enter the blood stream in undigested form — an advantage in cases of milk sensitivity.
4. Enriched with vitamin D by exposure to ultra-violet rays — insuring more efficient utilization of calcium and phosphorus.
5. Less expensive, costing the patient generally half the price of ordinary milk, and about one-third the price of cream.

Samples and literature will be sent on request.

F. H. PAXTON & SONS, INC.

459 E. Ohio St. Chicago, Ill.

pressure with a markedly lowered bleeding volume. In three cases the hemoglobin rose to 177, 178 and 190 per cent respectively. There was also an increase in the blood non protein nitrogen. As the peritonitis developed there was an enormous effusion of blood stained fluid into the peritoneal cavity. This fluid clotted spontaneously and was chemically similar to blood plasma.

Because of the aforementioned work it was thought that the secondary shock factor may be of importance in death due to intraperitoneal insertion of tissues. Experiments were therefore performed with this in mind. Liver and muscle were placed in the peritoneal cavity and subcutaneously. As a result of these experiments the following conclusions were reached. At least five lethal factors in experimental peritonitis due to bile or to implanted liver may be active; (a) local irritant action of the foreign substance producing plasma loss and secondary shock; (b) local damage to body tissues with absorption of toxic products produced; (c) action of absorbed products on general vascular permeability furthering secondary shock.

The plasma loss and secondary shock seem to be of more importance in death than any of the other factors.

Francis D. Murphy, Milwaukee.

SURGERY OF THE LOWER COLON AND RECTUM

RANKIN, FRED W.

"Concerning Colostomy." South. Med. Jour., 29:130-137, Feb., 1936.

In a well illustrated article, the Author gives an exceedingly practical discussion of colostomy, including an interesting historical sketch. The indications are two, one as a part of an extirpative (or palliative) procedure for cancer and the other as a decompressive measure for some benign obstruction such as imperforate anus or some benign inflammatory lesion such as diverticulitis. The two types of operation now used are first, the loop colostomy and second, the single-barreled or end colostomy. Three factors influencing the subsequent comfort of the patient and care of the openings seem important in the Author's experience. They are: first, taking all the slack out of the bowel so that it is pulled down from above as far as its mesenteric attachments will permit; second, bringing the bowel out through a small incision, usually a stab wound in the left groin; and third, bringing the lumen of the bowel (in a loop colostomy) entirely outside of the abdominal cavity. The site of the artificial anus may be varied, the usual locations being in the upper or middle portions of the low mid-line incision, at the site of the umbilicus which has been removed, or through a stab wound in the left groin, the latter location being favored by the Author. An elastic belt with a removable rubber section is preferred to any of the various cups, belts, etc., usually recommended. Sphincteric control of the new anus is declared to be impractical, the satisfactory care of the colostomy depending upon attention to diet and cleanliness of the stoma. Of great importance, too, is the attitude of the patient—and physicians and surgeons are urged to be less pessimistic in their discussion of this operation. It is a necessary procedure and one which is not incompatable with social and professional activities.

J. Duffy Hancock, Louisville.

COLLAR, FREDERICK A., AND RANSOM, HENRY K.

The One Stage Procedure of the Treatment of Carcinoma of the Rectum. Ann. Surg., 104:4, 636, 645.

Out of 270 cases of carcinoma of the rectum seen by the authors in the past six years, 221 accepted some kind of treatment. Fifty-one per cent of these were unsuitable for radical operation because of far advanced lesions or associated diseases. Palliative colostomy was done in 75 cases because it is considered of definit value. Seventy-two cases were treated by the one stage abdominoperineal procedure and 27 by the two stage procedure.

To the author's "it appeared that the second stage of this operation was as long and as difficult as the one stage operation and the mortality of the one stage procedure should not be higher because of operative trauma if the patient could be brought to operation in as good condition."

Emphasis is placed on preparation of the patient with weak saline purges, daily enemata, bed rest most of the time, low residue, high caloric diet with high fluid intake, and blood transfusion if indicated for anemia. Bactrogen (Steinberg) was used preoperatively or more recently at the time of operation. The average period of preparation was seven days.

The operative procedure follows the method of Miles and Rankin. A long free end of the proximal colon allows early opening of the bowel without danger of wound infection. The excess bowel is removed after the wound has healed. A spinal anesthetic consisting of 80 mg. of novocaine and 20 mg. of pantocaine is administered.

In spite of the fact that the prone position with the hips flexed gave better exposure for the perineal part of the procedure the authors chose the Sims position because a fall of blood pressure was too often encountered when the former position was employed.

Reviewer's Note:

The question of a one stage or a two stage operation must be answered by

Control gastric hyperacidity without the use of alkalies!

AMPHOJEL

Wyeth's Alumina Gel

ANTACID—ADSORBENT

Amphojel, Wyeth's Alumina Gel, is a creamy palatable colloidal suspension of hydrated alumina—$Al_2(OH)_6$—capable of neutralizing in one hour not less than 12 volumes of gastric juice containing 0.36% hydrochloric acid. Thus, a teaspoonful will *neutralize to Toepfer's reagent* over one and one-half fluid ounces of such juice or a corresponding amount of stronger secretion.

Even excessive use of Amphojel will not cause gastric alkalinity, altered pH of the blood stream or secondary acid rise.

Indicated for the control of gastric hyperacidity

IT ABSORBS TWICE ITS WEIGHT IN WATER*

Kellogg's ALL-BRAN is the natural laxative food that *prevents and relieves common constipation due to* meals low in "bulk."

This simple test shows how ALL-BRAN functions: fill a glass 4/5 full of ALL-BRAN. Pour water up to the brim of the glass. Soak 15 minutes, and drain off excess water. Feel the water-softened mass. It's much like a soft sponge. In fact, laboratory tests* show that ALL-BRAN absorbs at least twice its weight in water.

Within the body, this water-softened "bulk" gently "sponges" out the system. ALL-BRAN also provides vitamin B to tone up the intestinal tract, and iron for the blood.

The "bulk" in Kellogg's ALL-BRAN is much like that in leafy vegetables. But with many people, the "bulk" in fruits and vegetables is largely broken down in the system . . . and intestinal muscles get too little exercise. Gentle-acting ALL-BRAN fiber does not break down. So it is much more satisfactory.

ALL-BRAN may be served as a cereal, or cooked into appetizing muffins, breads, etc. It is sold by all grocers. Made by Kellogg in Battle Creek.

*Tests made by Samuel P. Sadtler & Son, Inc., Analytical Chemists, Philadelphia, Pa

Eat Kellogg's ALL-BRAN regularly for regularity

the surgeon who does the operation. The surgeon with less experience will do more two stage operations and the one stage operation will be carefully selected. Those who have more experience will find a larger number satisfactory for the one stage procedure but even among surgeons with wide experience the two stage operation will still have a place in poor risks. Some support of this contention may be deduced from the authors' statement that "in the one stage operation the difficulties of regulating the colostomy are superimposed upon a patient recovering from a severe operation." Perhaps the removal of this burden would swing the balance from failure to success in some bordering cases.

FELSEN, JOSEPH.

Acute and Chronic Bacillary Dysentery. Amer. Jour. Path., XII, 3, p. 395, May, 1936.

A study based primarily upon the Jersey City epidemic of bacillary dysentery of 1934 is presented. The author's main purpose has been (1) to stress the fact that acute bacillary dysentery is a systemic disease in which the pathological lesions are caused by one or more toxins affecting, as well, extraenteric organs; that the intestine alone need not bear the main brunt of the infection; and (2) that the late manifestations of the disease bear a very close relationship to non-specific ulcerative colitis.

It is believed that the intestinal lesions in the human are due to the excretion of the dysentery toxin, circulating in the blood stream, through the bowel wall. It is believed, too, that the toxin may be reabsorbed and repeat the cycle. The terminal ileum and colon seem to have a predilection for the toxin as the greater lesions are found there, although any portion of the bowel may be involved. An enteric and a neurotropic toxin have been isolated by Olitsky and Kligler. Clinical evidence exists which points to the presence of an arthritic and a myelotropic toxin also. The frequent association of labial herpes suggests, too, the presence of a virus. Examinations of the spinal fluid and the fluid from joints have failed to show the presence of microorganisms. In the chronic type of disease with arthritis, the acute dysentery infection having long before subsided, the joint involvement is probably due to a streptococcus or streptococcic toxin. The enterococcus is often recovered from the stools and other materials. A marked toxic granulocytopenia is at times observed. As the bone marrow in two cases coming to autopsy showed no evidence of deficiency in granulocyte formation, it was concluded the destruction of the leucocytes took place in the peripheral blood or in the vascular sinusoids of the bone marrow into which the granulocytes must migrate after their extravascular formation. Therefore the toxins of B. dysenteriae should be considered from the standpoint of selectivity as enteric, neurotropic, arthritic, and myelotropic. The Shiga-Kruse, Flexner, Hiss and Sonne-Duval strains all enter into the general picture.

The intestinal lesion in the acute dysentery begins as a definite hyperemia of the mucosa of large and small intestine with moderate edema and diffuse lymphoid hyperplasia of the solitary acuminate lymph nodules. Peyer's patches are similarly involved. The goblet cells pour out quantities of mucus, apparently for protection. On the second and third days blood oozes through the relatively intact epithelium. Superficial mucosal ulceration takes place—the lymph nodes become larger and central necrosis appears. The mild case usually does not extend beyond this stage. As the terminal ileum is severely affected patients have been on occasion operated upon for acute appendicitis—the mesenteric lymph nodes are then seen to be large, soft and pinkish in color. The acute stage usually subsides by the end of the third week. Continuing intestinal symptoms indicate chronicity and probably secondary non-specific intramural infection. The mucosa bleeds easily on examination, ulcers appear, and, as time goes on, the submucosa and deeper layers become involved, the

"IT'S NOT THE OIL . .

it's the *Vitamins*"

●Cod liver oil was used for many years before the discovery that the therapeutic activity rested in the fat-soluble vitamins A and D rather than the oil itself.

You may now prescribe the natural vitamin potency of cod liver oil, stripped of the unpleasant oily bulk, in a compact, palatable form—White's Cod Liver Oil Concentrate.

When you prescribe White's Cod Liver Oil Concentrate, you are not substituting—you are providing the natural vitamin potency of cod liver oil devoid of the disagreeable "excess baggage."

Assuring Obedient Patients

When long continued administration of a medicament is desired, full cooperation of the patient is necessary. Any factor which will increase palatability and convenience will also aid in assuring routine administration. Particularly is this true for the following patient types:

The Infant—in whom the fear of the teaspoon has been instilled by parents.

The Child—who rebels at the unpalatable fatty bulk of cod liver oil.

The Convalescent—whose appetite is disturbed by bulky and unpleasant medication.

The Pregnant Mother—who needs the cod liver oil vitamins but cannot tolerate the oily or fatty portion of cod liver oil.

Patients of all ages will gladly accept the three economical, pleasant dosage forms of White's Cod Liver Oil Concentrate.

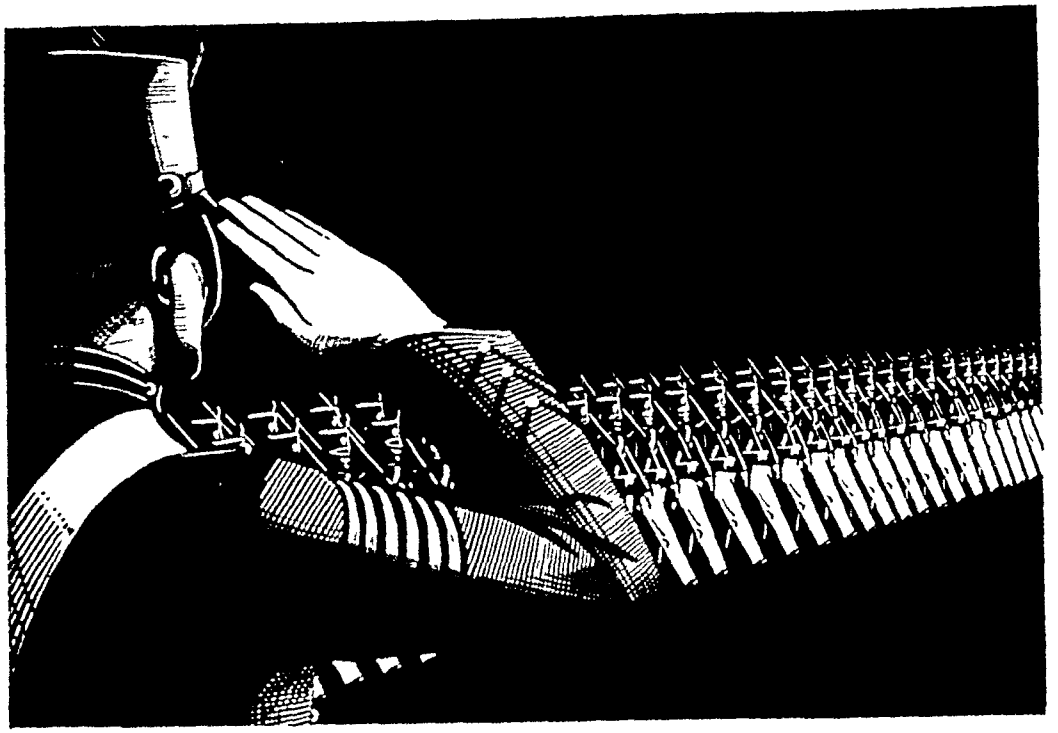
wall thickened, haustration eliminated, pseudopolyposis may occur, etc.—the picture of chronic ulcerative colitis.

Follow up studies of cases of acute bacillary dysentery have shown that in some patients intestinal lesions persist long after the dysentery organism has disappeared from the feces. The longest period of observation was 4 years. In the Jersey City epidemic 122 cases out of a total of 210 hospitalized patients were examined 9 to 12 months after the acute attack; 18.8 per cent gave evidence of chronic ulcerative colitis. Epidemiological studies revealed definite contact and familial incidence in non-specific ulcerative colitis and a geographic distribution corresponding to that of bacillary dysentery. Positive agglutination titers against B. dysenteriae were obtained in 62 consecutive cases of non-specific ulcerative colitis, in 2 of non-specific granuloma, and in 14 cases of chronic distal ilcitis. Control studies of 300 serums showed diagnostic titers in 4.6 per cent.

The laboratory diagnosis depends upon: 1. fecal culture —the specific dysentery organism is often isolated only during the first week; 2. diagnostic fecal bacteriophage; and 3. agglutination titer. The second begins to appear in the feces and the agglutination titer to rise in the blood after this time.

The character and modification of the dysentery toxins suggest that to be effective therapeutically, a specific serum must be used within the first few days when the major intestinal lesions occur. It should be an anti-toxin effective against known toxins that have been properly standardized by biological methods. Active immunization must be directed chiefly against the secondary non-specific invaders.

N. W. Jones, Portland, Oregon.



WOOLF, MONTAGUE S.

Operations for Cancer of Rectum. Amer. Jour. Surg., 35:1, 79-82, Jan., 1937.

In 1828 the first amputation of the rectum was done by an encircling incision around the anus, dissection close to the rectal wall and cutting across the bowel. The first advance was to remove the coccyx and suture the anus to prevent sepsis.

The first excision was planned by Sir James Paget in 1878. In 1884 Harrison Cripps reported three cases of perineal excision. In 1885 Kraska removed part of the sacrum but preserved the sphincter and pulled the bowel above the excision into the sacral wound. This operation was used almost universally for over 20 years.

By 1900 W. Ernest Miles was convinced that an abdomino perineal operation was necessary to remove the wide spread invasion in rectal growths. This operation gives the greatest insurance against recurrence but it is also the operation to which most patients succumb. W. J. Mayo, in 1912, reduced the mortality from 35% in the Miles type of operation to 13.3% by doing a single barrel colostomy and inverting the distal segment for later removal. Fatal sepsis often followed because of gangrene of the distal segment resulting from interference with its circulation. Coffey reported a 5% mortality with his quarantine drainage of the peritoneal space in which the dead segment of bowel lay. In 1915 D. Jones was able to remove more of the sigmoid from the perineal approach by freeing the sigmoid in the abdomen, being careful to preserve its blood supply, reconstructing the pelvic peritoneum at a higher level, doing a loop colostomy, and removing the rectum and sigmoid later. His mortality was 22%. Lockhart Mummery performs a loop colostomy then removes the rectum from the perineum by wide dissection after removal of the coccyx. His mortality in private cases is 3% and in charity cases it is 14%. Lahey makes a single barrel colostomy in the iliac region and implants the distal segment in the exploratory wound. Later the distal opening is closed and an abdomino perineal removal is done. This procedure allows for cleansing of the lower

☆ DISCIPLINE ☆

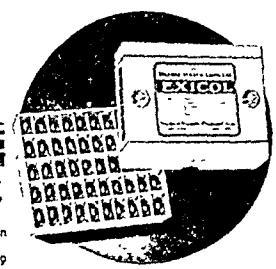
"Discipline is the development of the faculties by instruction and exercise." When functions such as habit time of bowel movement are neglected through lack of discipline or intelligence, they require careful training to restore them to a normal state.

Petrolagar has proved to be an agreeable and effective means of assisting in the establishment of bowel discipline. Because Petrolagar mixes intimately with the bowel contents, it increases the bulk in the stool to a soft mass which is easily passed.

Petrolagar is prepared in five types — providing the doctor with a variation of treatment to suit the individual patient. Petrolagar Laboratories, Inc., Chicago, Ill.

Petrolagar is a mechanical emulsion of pure liquid petrolatum (55% by volume) and agar agar Accepted by the Council on Pharmacy and Chemistry of the American Medical Association for the treatment of constipation

Petrolagar



Proven
CHOLERETIC and CHOLAGOGUE
EXICOL

Authorities agree that choleretics, whether bile salts or bile acids, are not cholagogues (they do not stimulate gall bladder evacuation).* The effective and proven cholagogues are fats and fatty acids.**

containing both a fatty acid (oleic acid) and bile salts, is a true cholagogue and choleretic.

Furthermore ... it was definitely proven that the addition of oleic acid to bile salts (Exicol) increases bile secretion from the liver 100 to 200%.***

EXICOL fulfills the necessary requirements for the adequate management of diseases of the biliary tract.

segment but the abdomen is entered twice. Rankin and Gabriel perform a perineo abdominal operation, the first stage consisting of a loop colostomy and the second stage consisting of a perineal dissection and a placing of the rectum in the peritoneal cavity from which it is removed by an abdominal incision. Objections to this method are that two abdominal operations are required, accidental opening of the rectum would contaminate the peritoneal cavity, and the abdominal procedure is done late in the operation which might offer anesthetic difficulties especially with the use of "thecal analgesia."

Previous to 1926 these kind of cases were operated on by many staff surgeons and since then they have been operated on chiefly by one surgeon who is responsible for proctologic cases. Since the present arrangement has been in force the operative mortality has been reduced from 16.2% to 2.6%. In 38 operable cases the author reports a five year survival of 26% following the perineal resection of Mummery in comparison with a 21.7% five year survival in 46 cases resected previous to the organization of the proctologic service.

The operations used by the author are colostomy followed by posterior resection and the one stage abdomino perineal. The latter operation has not yet been used to its fullest value.

BRINALEY, G. V.

Carcinoma of the Rectum. J. A. M. A., Vol. 108, pp. 37-43, Jan. 2, 1937.

Practically all patients with carcinoma of the rectum can be cured if the diagnosis is made early enough and the proper surgical procedures carried out. The diagnosis is comparatively easy when the proper methods are used.

The prognosis after diagnosis depends upon the extent of the lesion. The length of time that a rectal carcinoma remains localized after the onset of symptoms varies from six to eighteen months, averaging 9.4 months. Extension occurs by direct continuity with other tissues, by lymphatic invasion and occasionally through the blood stream. The symptoms and signs of the disease are melena, a mild rectal discomfort, characterized by a feeling of heaviness, soreness or a mild cramping. Intense pain is practically never an early manifestation of the disease. In some cases there is a change in the bowel habit. Digital and proctoscopic examination usually aid materially in the diagnosis.

Statistics show that the degree of malignancy of rectal neoplasms are of grades one or two in approximately 50 to 75 per cent of the cases. The type of operation to be performed depends upon the degree of malignancy. More radical surgery should be performed for the lower grades of malignancy than the higher grades, even though the former appeared to be more advanced. Neoplasms of a highly malignant degree and of the borderline operability are treated preferably by radium and roentgen rays rather than by surgery. Lesions that are moveable or which have not metastasized to the regional lymph glands are definitely better risks. In addition, the sex, the age and the general physical condition influences the prognosis and the type of surgery to be performed. The mortality rate in the male is higher than in the female because of the smaller and therefore less accessible pelvis and the fact that the pelvic peritoneum is less resistant in the male.

The author believes that a graded operation divided into two or more stages is usually preferable. Most cases require an abdominoperineal resection in two stages, but some only require an abdominal approach. The author also believes that the electrocautery knife should be used in almost all cases. X-ray and radium treatment he believes should be reserved for inoperable cases and those who refuse operation.

Francis D. Murphy, Milwaukee.

HOW OVALTINE AIDS GASTRIC STARCH DIGESTION

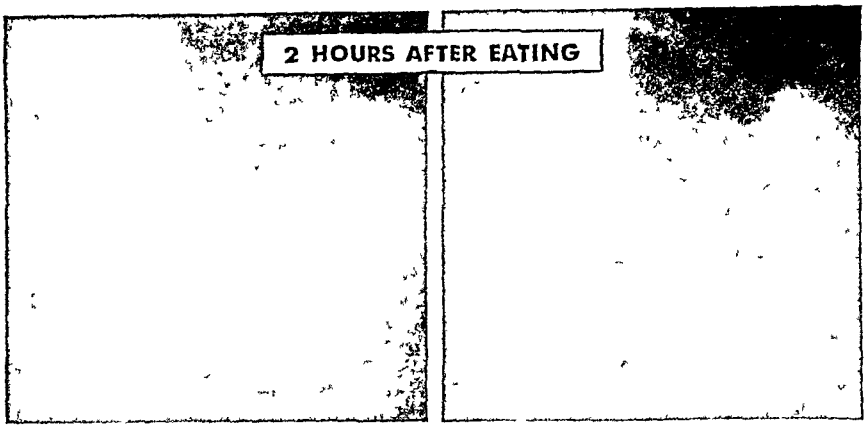

FIGURE 1—STARCH MEAL ALONE

FIGURE 2—STARCH MEAL WITH OVALTINE

THE accompanying x-rays show the relative size of the gastric contents 2 hours after the ingestion of a starch meal alone (figure 1) and a starch meal with OVALTINE added (figure 2).

The average decrease in gastric contents in 12 normal human subjects due to OVALTINE was 20%.

The facilitation of gastric evacuation of starches by OVALTINE took place *in the presence of normal salivary digestion.* This is due to the fact that salivary amylase is inactivated at pH 4.5, whereas malt amylase is not destroyed until the acidity of pH 2.5 is reached. OVALTINE *continued to digest the starch after salivary digestion had stopped.*

Clinical Application

It is not intended that these results be applied to *normal* individuals. However, for the person who bolts his foods without proper mastication, or for the person who suffers from an inadequate secretion of saliva or pancreatic juice, the addition of OVALTINE to the diet is indicated.

OVALTINE is an effective and standardized product for supplying additional starch-digesting enzymes in a pleasant and economical form.

Try OVALTINE

If you would like to recommend Ovaltine . . . *to some patient with faulty starch digestion, we will send a large size can prepaid to your office, or to the patient direct if you prefer. Please address The Wander Company, 180 North Michigan Avenue, Chicago, Illinois. Dept. D.N.2.*

Pablum is rich in minerals and vitamins. It is noteworthy that the calcium - phosphorus ratio of Pablum is 1.2:1, similar to that of average whole milk, which is considered the most favorable ratio for retention.

These figures are included to illustrate ordinary nutritional values. Calories, carbohydrates, fats, and proteins no longer constitute a serious nutritional problem.

†PABLUM (Mead's Cereal, thoroughly cooked) contains nine minerals (principally calcium phosphorus, iron, and copper) and vitamins B and G in substantial amounts—in addition to abundance of protein, fat, carbohydrate and calories. Pablum is palatable and requires no further cooking. Supplied in 1 lb. packages.

Daily Variations in the Concentrations of Acid and Pepsin in the Gastric Juice of Three Persons Observed for Two Months—*Walter C. Alvarez, M.D., Frances R. Vanzant, M.D. and Arnold E. Osterberg, Ph.D.* 162

The Influence of Mucoitinsulfuric Acid on Peptic Digestion—*S. A. Komarov, M.D., Ph.D.* 164

Pyloroplasty, Gastro-enterostomy and Partial Parasympathetic Denervation of the Pyloric Sphincter, and Their Relation to the Emptying Time of the Stomach—*George Crisler, M.D., Ph.D. and E. J. VanLiere, M.D., Ph.D.* 167

Extensive Resection of the Small Intestine in the Rat with Special Reference to Anemia—*Howard L. Alt, M.D., Ph.D.* 169

Studies on Auto-Digestion. VI. The Digestion of Living Tissues in Stomach Juice (Claude Bernard's Experiment)—*M. H. Maskin, MrD., R. Callahan and H. Necheles, M.D., Ph.D.* 174

Pancreatic Enzymes and Tissue Metabolism—*H. C. Bradley, Ph.D. and Samuel Belfer, M.D.* 220

The Influence of Bact. Coli and Its Products on the Motility of Strips of Excised Intestine—*Louis Weinstein, M.D. and Leo F. Rettger, M.D.* 224

Observations on Ulcerations Adjacent to Experimental Gastric Pouches in Dogs—*Asher Winkelstein, M.D.* 229

An Improved Gastric Test Meal—*Charles M. Wilhelmj, M.D., F. T. O'Brien, M.D. and Frederick C. Hill, M.D.* 319

The Fate of Bacteria Injected Directly into the Cecal End of the Colon—*Louis Weinstein, M.D.* 397

The Nature of Peptic Ulcerations—*M. E. Steinberg, M.S., M.D.* 399

Studies in Absorption of Undigested Proteins in Human Beings—*Irving Gray, M.D. and Matthew Walzer, M.D.* 403

Nocturnal and Diurnal Variations in the Acidity of the Spontaneous Secretion of Gastric Juice—*Frances A. Hellebrandt, M.D., Rubye H. Tepper, M.S., Helen Grant, M.S. and Ruth Catherwood, M.S.* 477

On the Inhibitory Effect of Corpus Luteum on Gastric Secretion—*Ina A. Manville, M.D., Ph.D. and Walter R. Munroe, B.S.* 482

An Investigation into the Production of a Proteolytic Ferment in the Duodenum which will Increase the Anti-anemic Efficacy of Liver: Its Relationship to the Cause of Pernicious Anemia—*Garnett Cheney, M.D.* 541

Histidine in Experimental Gastric Ulcer—*Charles Windwer, M.D. and Milton J. Matzner, M.D.* 547

Studies in Bowel Drainage—*Anton W. Oelgoetz, M.D., Paul A. Oelgoetz, B.A. and J. Wittekind, R.N.* 549

The Elimination of Various Dyes from the Pavlov Pouch of Dogs—*Samuel Morrison, M.D., David L. Reeves, M.D. and Raymond E. Gardner, Sc.D.* 551

The Proteolytic Effect of Normal Gastric Juice on Beef Muscle Globulin, with Reference to the Reported Action of the Anti-anemic Intrinsic Factor—*Charles P. Emerson, Jr., B.S. and O. M. Helmer, Ph.D.* 753

The Changes within the Cells of the Gastric Mucosa During Secretory Activity—*Abraham J. Gitlitz, M.D. and William Levison, M.D.* 756

Prophylactic Treatment of Peptic Ulcers Produced Experimentally by Cinchophen—*Leonard K. Stalker, M.D., Jesse L. Bollman, M.D. and Frank C. Mann. M.D.* 822

The Composition of Human Gastric Juice Secreted in Response to Histamine Administration—*C. Gwendoline Toby, B.A.* 896

Does Histamine Stimulate the Secretory Activity of the Peptic Cells in Man?—*C. Gwendoline Toby, B.A.* 902

Gastro-Intestinal Studies—*Paul J. Fouts, M.D., O. M. Helmer, Ph.D. and L. G. Zorfas, M.D.* 904

Studies on the Chemical Nature of the Interaction Between the Intrinsic and Extrinsic Anti-anemic Factors Upon Incubation of Liver Extract and Normal Gastric Juice—*O. M. Helmer, Ph.D. and Charles P. Emerson, Jr., B.S.* 906

SECTION III—NUTRITION

The Influence of Fruit Ingestion Before Meals Upon the Bacterial Flora of Stomach and Large Intestine and on Food Allergins—*Olaf Bergeim, M.D., Arthur Hanszen, M.D. and Lloyd Arnold, M.D.* 45

The Effects on the Gastric Juice of Man of Six Weeks' Deprivation of Vitamin B_1—*Walter C. Alvarez, M.D., Frederick Pilcher, M.D., Mary A. Foley, Annette Mayer and Arnold E. Osterberg, Ph.D.* 102

A Survey of Four Hundred Ninety Diabetic Admissions to General Hospitals—*Lemuel C. McGee, Ph.D., M.D.* 178

Ketosis as Measured by the Ketonemia Following Fat Ingestion by Obese and Non-obese Patients—*Edmund L. Keeney, M.D., James W. Sherril, M.D. and Eaton M. MacKay, M.D.* 231

Is Gastric Secretion or Digestion Impaired by a Mixture of Carbohydrate and Protein in the Diet?—*Harry Shay, M.D., J. Gershon-Cohen, M.D., M.Sc. (Med.) and Samuel S. Fels, M.D.* 235

Clinical Aspects of Vitamin B-Complex Deficiency in Association with Disease of the Gall Bladder, Report of an Instance—*G. Louis Weller, Jr., M.D.* 324

Mucous Colitis, Complicated by Colonic Polyposis, Relieved by Allergic Management, Report of an Instance—*L. P. Gay, A.B., M.D.* 326
Selenium-Toxicosis: The Etiologic or Causative Factor in Pellagra?—*R. de R. Barondes, M.D.* 330
The Chemical Nature of the Anti-Anemic Principle—*Julius Schultz, B.S.* 405
Experimental Gout in Turkeys—*Jesse L. Bollman, M.D. and Carl F. Schlotthauer, D.V.M.* 483
Spontaneous Hyperinsulinism Due to Pancreatic Adenoma in a Patient with Carcinoma of the Sigmoid (A Catastrophic Conjunction)—*Charles-Francis Long, M.D., L. Sheplin, M.D. and D. B. Fishback, M.D.* 488
Enzymic Efficiency in Avitaminosis. III. Influence of Vitamin B_1 and G Deficiencies on the Concentration of Blood and Tissue Enzymes—*M. C. Kik, Ph.D., Barnett Sure, Ph.D. and Kathryn Sue Buchanan, M.S.* 490
Enzymic Efficiency in Avitaminosis. IV. Influence of Vitamin A Deficiency on Concentration of Blood and Tissue Enzymes—*Barnett Sure, Ph.D., M. C. Kik, Ph.D. and Kathryn Sue Buchanan, M.S.* 493
On the Probable Frequency of Allergic Shock—*Warren T. Vaughn, M.D. and David M. Pipes, M.D.* 558
The Clinical Significance of Indicanuria—*Horace W. Soper, M.D., F.A.C.P.* 564
Vitamin Deficiency in Prescription Diets of Diabetics—*Anthony Sidoni, Jr., M.D.* 759
Vitamin B. Complex Therapy in Chronic Arthritis—*Charles LeRoy Steinberg, M.D.* 765
The Effect of Vitamin D on Intestinal Atony of Rickets—*Lester Yoder, M.S.* 828
The Effect of Vitamin D on Intestinal Iron Reduction—*Lester Yoder, M.S.* 829
Protamine Insulin in the Treatment of Diabetes—*Harry G. Jacobi, M.D.* 908
The Present Evaluation of Vitamin B_1 Therapy—*Martin G. Vorhaus, M.D.* 915

SECTION IV—ROENTGENOLOGY

Newer Interpretations of Gall Bladder Function and Their Diagnostic and Therapeutic Application—*Maurice Feldman, M.D. and Samuel Morrison, M.D.* 52
Roentgenographic Studies of the Mucous Membrane of the Colon. I. The Normal Pattern—*Franz J. Lust, M.D. and Harry G. Jacobi, M.D.* 108
Radiological Demonstration of an Allergic Reaction in the Mucosa and Musculature of the Colon—*L. P. Gay, A.B., M.D., F.A.C.P.* 181
Functional Changes of the Vermiform Appendix Producing Diverticular Saeculation of the Spastically Contracted Organ—*A. Galambos, M.D.* 412
Roentgenographic Studies of the Mucous Membrane of the Colon. II. Colitis—*Franz J. Lust, M.D.* 194
The Roentgen Diagnosis of Acute Intestinal Obstruction—*Jacob Buchstein, M.D. and Leon Michaels, M.D.* 767
The Importance of Preliminary Films in a Routine Examination of the Abdomen—*I. Klein, M.D.* 832
Carcinoma of the Tail and Body of the Pancreas—*Morris A. Hardenson, B.D., M.D.* 835
Large Diverticula of the Gastric Cardia—*Garnett Cheney, M.D.* 920
Volvulus of an Inverted Intrathoracic Stomach Complicating Diaphragmatic Hernia: Case Report—*Arthur Bower, M.D.* 923

SECTION V—THERAPEUTICS

Clinical Results in the Medical Treatment of Chronic Ulcerative Colitis—*Everett D. Kiefer, M.D.* 56
Aluminum Hydroxide as an Antacid in Peptic Ulcer—*W. Lloyd Adams, Ph.D., I. H. Einsel, M.D. and Victor C. Myers, Ph.D., D.Sc.* . . . 112
Phenolphthalein Administration to Nursing Women—*Bernard Fantus, M.D. and J. M. Dyniewicz* 181
I. Effect of Acetylsalicylic Acid Upon Gastric Activity and the Modifying Action of Calcium Gluconate and Sodium Bicarbonate—*J. G. Schnedorf, M.D., W. B. Bradley, M.D. and A. C. Ivy, M.D.* 239
II. Effect of Prolonged Administration of Salicylate Upon Nitrogen Metabolism and Plasma Carbon Dioxide Combining Power in the Dog—*J. G. Schnedorf, M.D., W. B. Bradley, M.D. and A. C. Ivy, M.D.* 332
Glutamic Acid Hydrochloride as a Substitute for Dilute Hydrochloric Acid in Achlorhydria—*Paul K. Wosika, M.S., M.D.* . 335
Phenolphthalein Studies. III. Phenolphthalein and Activated Charcoal—*Bernard Fantus, M.D. and J. M. Dyniewicz* 337
III. The Rate of Absorption of Salicylates and the Effect of Certain Compounds on the Rate of Absorption of Acetylsalicylic Acid from the Stomach and Intestine—*W. B. Bradley, M.D., J. G. Schnedorf, M.D. and A. C. Ivy, M.D.* 415
The Control of Gastric Acidity in Peptic Ulcer by Alkalinized Powdered Whole Milk Tablets—*Paul H. Wosika, M.S., M.D.* 419
The Pathology and the Treatment of Intestinal Amebiasis—*Thomas T. Mackie, M.D.* 566
Pectin as a Detoxification Mechanism—*Ira A. Manville, M.D., Ph.D., Elizabeth M. Bradway, Ph.D. and Avoca S. McMinis.* 570
Phenolphthalein Studies. IV. Phenolphthalein Solubilities—*Bernard Fantus, M.D. and J. M. Dyniewicz, Ph.D.* 573
Bile Salt Therapy in Liver and Gall Bladder Disease—*Bernard D. Rosenak, M.D. and Kenneth G. Kohlstedt, M.D.* 577
What Drug Best Kills Hookworms?—*Clayton Lane, M.D.* 770
The Spastic Colon Diet—*Edward E. Cornwall, M.D., F.A.C.P.* 773
The Etiology and Therapy of Ulcerative Colitis—*Asher Winkelstein, M.D.* 839
Chaulmoogra Oil in the Treatment of Lymphopathia Venerea—*George M. Landrock, M.D.* 928

SECTION VI—ABDOMINAL SURGERY

A Review of 746 Gastric and Duodenal Ulcers—*J. William Hinton, M.D., F.A.C.S.* 59
Electro-Cholecystocausis: Preliminary Report—*Lester R. Whitaker, M.D.* 62
Diverticula of the Jejunum: Report of Four Cases—*Thomas J. Jones, M.D. and George Crile, Jr., M.D.* 120
The Pathological Physiology of the Stomach Following Sub-Total Gastrectomy for Gastro-Duodenal Ulcer—*Fernando Milanes, M.D.* 186
Problems in Obstructive Jaundice Cases—*D. Philip MacGuire, A.B., M.D., F.A.C.S.* 244
Experimental Peptic Ulcer—*Charles A. Flood, M.D. and Clinton R. Mullins, M.D.* 249

SECTION VII—SURGERY OF THE LOWER COLON AND RECTUM

The Technique of the Local Injection of Saline Solution for the Relief of Pruritus Ani—*Wm. J. Schatz, M.D. and Vaughan Sprenkel, M.D.* 63
Annual Abstracts of Proctologic Literature—*Clement L. Martin, M.D.* 65, 123, 191, 258, 317, 500, 586

Ischio-Rectal Abscess: A Stage in the Development of "Horseshoe" Fistula: A Case Report—*George M. Landrock, M.D.* 122
Perianal Lipoma: A Case Report—*Max I. Lomas, M.D.* 123
Anal Cryptitis—*Paul C. Blaisdell, M.D.* 188
The Present Status of Radiation Therapy in Carcinoma of the Anus, Rectum and Sigmoid Colon—*Harry E. Bacon, M.D., F.A.C.S.* 255
Superior Peri-Rectal Abscesses—*J. Hall Allen, A.B., M.D.* 341
Elbow Deformity of the Colon—*Jerome Morley Lynch, F.A.C.S., M.D. and G. Johnson Hamilton, M.R.C.S., M.D.* 344
A New Sigmoid Cannula—*Z. Bercovitz, M.D.* 499
Clinical and Therapeutic Status of Cases of Colonic Diverticulosis Seen in Office Practice—*J. H. Willard, M.D. and H. L. Bockus, M.D.* 580
Anal Fissure, Anal Spasm and Anal Stenosis—*E. A. Daniels, M.Sc., M.D.* 775
The Variety and Distribution of Gross Lesions in Lymphopathia Venerea—*Collier F. Martin, M.D., F.A.C.S.* 844
Lymphogranuloma Inguinale—*Manuel G. Spiesman, M.D., Robert C. Levy, M.D. and David M. Brotman, M.D.* 931
Hemorrhoids: Their Origin and Treatment—*Jerome M. Lynch, F.A.C.S., M.D., Vincent Hurley, F.R.C.S., M.D. and G. Johnson Hamilton, M.R.C.S., M.D.* 936
The Significance of the Icterus Index in Proctological Disorders—*J. Gerendasy, M.D. and R. V. Gorsch, M.D.* 940

SECTION VIII—EDITORIAL

Certain Pertinent Observations Upon Milk and Cholesterol as They Relate to Infection and to Arteriosclerosis—*Horace W. Soper, M.D.* 126
Photographic Aids in Conserving Space in Scientific Periodicals—*Walter C. Alvarez, M.D.* 192
Significance of Vitamin A Deficiency—*Ira O. Park, M.D.* 193
Allergy and Therapeutics—*Frank Smithies, M.D.* 194
What is an "Intractable" Peptic Ulcer?—*Albert F. R. Andresen, M.D.* 259
Abdominal Pain Due to Intracranial Disease—*Walter C. Alvarez, M.D.* 349
The All-Or-None Law and the Parietal Cells of the Stomach—*F. Hollander, M.D.* 428
Distal or Regional Ileitis, Ulcerative Enteritis—Not an Entity—*Moses Paulson, M.D.* 430
The Oelgoetz Conception of Allergy—*J. O. Crist, M.D. and Anton W. Oelgoetz, M.D.* 431
Concerning the Enigma, Peptic Ulcer—*Frank Smithies, M.D.* 501, 941
The Unknown Liver—*Lathan A. Crandall, Jr.* 587
A "News" Section for the Journal—*Frank Smithies, M.D.* 587
Endemic Dysentery: Significance and Diagnosis—*Burrill B. Crohn, M.D.* 784
A Bold Suggestion—*Beaumont S. Cornell, M.D.* 784
Gastric Acidity and Erythrocyte Count — *Eugene Foldes, M.D. and Frank L. Apperly, M.D.* 784
Introducing Volume IV—*Beaumont S. Cornell, M.D.* 944

SECTION IX—BOOK REVIEWS

Medical Treatment of Gall Bladder Disease—*Martin E. Rehfuss, M.D. and Guy M. Nelson, M.D.* 66
The Patient and the Weather—*William F. Peterson, M.D.* 195, 588
Exploration Radiologique Des Colons Et De L'Appendice—*Drs. Gorges Maingot, Raymond Sarasin and Henri Duclos* 259
"Medical Papers," Dedicated to Henry Asbury Christian 262
Uber Die Rhythmik Der Leber-Funktion, Des Stoffwechsels Und Des Schlafes—*Erik Forsgren, M.D.* 350
The Eleventh Revision of the United States Pharmacopeia and the Sixth Revision of the National Formulary—*A. C. Ivy, M.D.* 432
Experimental Enzyme Chemistry — *Henry Tauber, Ph.D.* 588
Disturbios Do Transito Duodenal—*G. S. DePaula E. Silva, M.D.* 785
Medical Classics—*Williams and Wilkins* 847
Physician, Pastor and Patient—*George W. Jacoby, M.D.* 847
Food, Fitness and Figure—*Jacob Buckstein, M.D.* 848
The Art of Ministering to the Sick—*Richard C. Cabot, M.D. and Russell L. Dicks, B.D.* 945

SECTION X—AFTER "HOURS"

Raoul Bensuade of Paris—*Martin J. Synnott, M.D.* 262
Causae Mortis—*Virgil E. Simpson, M.D.* 351

SECTION XI—SOCIETIES, PROGRAMS AND PROCEEDINGS

Program of the American Gastro-Enterological Association 68, 128
Asociacion Mexicanna De Gastro-Enterologia 69
In Memoriam: Ivan Petrovich Pavlov—*Andrew Conway Ivy, M.D.* 130
Thirty-Seventh Annual Meeting American Proctologic Society 196
American Proctologic Society—*Curtice Rosser, M.D.* 435

SECTION XII—"THE CLINIC"

Gastro-Duodenal Hemorrhage of Unknown Origin: A Case Report—*Charles D. Enfield, M.D.* 69
Treatment of Chronic Ulcerative Colitis: Report of Five Cases—*Emor L. Cartwright, M.D.* 70
General Abstracts—72, 133, 200, 272, 362, 445, 507, 595, 791, 854, 947
Gastric Carcinoma: Necessity for Earlier Diagnosis as Shown by Case Reports—*B. Markowitz, M.D. and M. D. Molay, M.D.* 131
Obstipation with Long Continued Vomiting: Effect on the Teeth—*J. Arnold Bargen, M.D. and Louie T. Austin, D.D.S.* 198
Amebiasis Associated with Carcinoma—*J. Arnold Bargen, M.D.* 268
Master Chart for Disease of the Biliary Tract—*William T. Doran, M.D. and Eilif C. Haussen, M.D.* 268
Moniliosis of the Respiratory and Digestive Tracts—*Oscar Berghausen, B.A., M.D.* 271
"Milk of Calcium Bile": A Report of Two Instances — *Benjamin M. Bernstein, M.D. and Daniel Diamond, M.D.* 360
Extra-Pancreatic Hypoglycemia — *John Francis Briggs, M.D. and Harry Oerting, M.D.* 436
Regional Ileitis—*F. Gregory Connell, M.D.* 438
Gastro-Intestinal Bleeding in Disease of the Liver and Biliary Tract—*S. S. Lichtman, M.D.* 439
Chronic Appendicitis—*William Fitch Cheney, M.D.* 504
Post-Operative Hemorrhage Following Acute Ruptured Pre-Pyloric Ulcer—*Gaston A. Carlucci, M.D., F.A.C.S.* 506
Intestinal Polyposis—*Joseph Felsen, M.D.* 589
Diffuse Polyposis of the Colon—*L. K. Ferguson, M.D.* 593
Multiple Primary Melanomas of the Small Intestine—*Frank R. Menne, M.D., F.A.C.P. and J. A. P. Beeman, A.B.* 786
Beriberi Due to a Reducing Diet—*Maurice Snyder, M.D.* 789
Primary Leiomyosarcoma of the Upper Third of the Esophagus—*Frank W. Menne, M.D., F.A.C.P. and Richard F. Birge, M.D.* 848

Hodgkin's Disease of the Pel-Epstein Type—*Ralph W. Mendelson, M.D. and E. E. Royer, M.D.* 851

PAPERS, WITH DISCUSSIONS, AS PRESENTED AT THE THIRTY-NINTH ANNUAL SESSION OF THE AMERICAN GASTRO-ENTEROLOGICAL ASSOCIATION, ATLANTIC CITY, N. J., MAY 4-5, 1936

President's Address—*Howard F. Shattuck, M.D.* 617
Cholesterol Metabolism in Jaundice—*S. Allen Wilkinson, M.D.* 618
Biliary Stasis—*Carl H. Greene, M.D., J. Russell Twiss, M.D. and R. Franklin Carter, M.D.* 622
The Treatment of Acute Hepatic Insufficiency and Its Relation to Prognosis—*Chester M. Jones, M.D.* 624
Chronic Hepatitis with Jaundice (Biliary Cirrhosis)—*James F. Weir, M.D. and Albert M. Snell, M.D.* 629
Macrocytic Anemia in Diseases of the Liver: General Considerations—*David H. Rosenberg, M.D.* 639
Anemia and the Gastro-Intestinal Tract: A Synopsis—*George R. Minot, A.B., M.D., S.D., F.R.C.P. (Edin.)* 643
Intubation Studies of the Human Small Intestine. VIII. Miscellaneous Observations—*T. Grier Miller, M.D., W. Osler Abbott, M.D. and W. G. Karr, Ph.D.* 647
The Components of the Gastric Secretion—*Franklin Hollander, Ph.D.* 651
Gastric Secretory Behavior in Chronic Gastritis—*J. F. Monaghan, M.D., H. L. Bockus, M.D., K. Kornblum, M.D. and G. R. Moffitt* 655
Intracutaneous Responses Comparable with Positive Frei Relations, with Colonic Exudate from Chronic Ulcerative Colitis Cases with Positive Frei Tests—*Moses Paulson, M.D.* 667
The Diagnostic Significance of Anti-Dysentery Bacteriophage—*Thomas T. Mackie, M.D.* 673
Certain Aspects of the Applied Physiology of External Pancreatic Secretion—*A. C. Ivy, Ph.D., M.D.* 677
Diseases of the Pancreas: The Clinical Aspect—*Thomas R. Brown, M.D.* 682
Surgical Aspects of Diseases of the Pancreas—*Daniel F. Jones, M.D.* 686
Thoracic Stomach with Short Esophagus and Diaphragmatic Hernia—*Leon Bloch, M.D., A. M. Seiby, M.D. and Samuel Salinger, M.D.* 689
Specific Food Sensitiveness—*Walter C. Alvarez, M.D.* 693
Certain Newer Methods of Treating Peptic Ulcer—*Andrew B. Rivers, M.D.* 698
Cystadenomata of the Pancreas: A Surgical Report—*B. Franklin Carter, M.D. and Louis Slattery, M.D.* 705
In Memoriam:
John Bryant—*Franklin W. White, M.D.* 707
Lafayette Benedict Mendel—*Victor C. Myers, Ph.D., D.Sc.* 708
Harlow Brooks—*William Gerry Morgan, M.D.* 709
Henry Wald Bettmann—*Leon Schiff, M.D.* 710
George Washington McCaskey—*William Gerry Morgan, M.D.* 711
Abstracts of Proctologic Literature—*Charles E. Pope, M.D.* 711

General Index for Volume Three

Abscess, ischio-rectal 122
peri rectal 311
Absorption, of protein 403
Acetocholine, effect on stomach 864
Achlorhydria 215, 335
Acid acetylsalicylic 239
glutamic 335
hippuric, test 459
hydrochloric 335, 428
hydrochloride 510
mucoitinsulphuric 161
salicylic, rate of absorption 415
variations 162
Acidity, gastric 391, 419
gastric and blood count 466
gastric and height and weight 83
nocturnal 477
with aluminum 879
Acidosis, diabetic 361
Adenoma, pancreatic 488
Adenomatosis coli 589
Alcohol, effect on digestion 452
test meals 881
Allergins, food 45
Allergy 191, 431
gastro-intestinal 131
block in 558
x-ray evidence 181
Alucol 880
Aluminum 879
cream 879
hydroxide 112
Amebas 526
Amebiasis, and cancer 268
treatment of 566
Ampula of Vater 280
Amylase 679
Amyloid disease 273
Anastomosis, biliary-intestinal 600
Anemia, after operations 8
and GI tract 643
hypochromic 645
in bowel resection 169
in gastritis 661
macrocytic 362, 638, 644
myelophthisic 851
pernicious 597
pernicious, gastric juice in 901
Anesthesia, spinal 123
Anoxemia and pyloric sphincter 94
Anthelmintic drugs 770
Antitoxins 559
Anus, fistula in 501
pruritus of 500
Apoplexy, abdominal 282
Appendicitis 272
Appendicitis, ac. pelvic 502
chronic 501
in small hospital 801
Appendix, diverticula of 412
Arteriosclerosis, in rats 280
Arthritis, Vitamin treatment of 765
Ascaridole 772
Aspirin 239
in allergy 560
rate of absorption 415
Atherosclerosis 365
Atony, intestinal 828

Auto-digestion 174
Avitaminosis 490, 493
Bacteria, colonic 397
in biliary disease 391
Bacteriophage 741
antidysentery 673
Bacterium coli 224
Basophilism, pituitary 73
Benzidrine sulphate 595
Beriberi, due to diet 789
Beta naphthol 771
Bile duct drainage 612
Bile, "milk of calcium" 360
pressure of 604, 606
salts 448
salt therapy 577
Biliary stasis 622
tract disease 268
Bleeding, gastro-intestinal 439
Blood chlorides 881
enzymes 679
Bodies, foreign 75
Botulism 273
Bowel, drainage of 549
Brain, trauma 381
Calcium carbonate 239
gluconate 418
Calculus, pancreatic 684
Cancer 124
and amebiasis 268
of pancreas 808
of pancreas head 596
of stomach 215
Cannula, sigmoid 499
Carbon tetrachloride 771
Carcinoma, anus 255
esophagus 370
gastric 131
gastric fever in 731
gastric resection in 808
Carcinoma, of colon 597
of esophagus 808, 858
of rectum 255
of sigmoid 255, 488
pancreas, x-ray in 835
rectum 614
Cardiospasm 1
Carotene 74
Cells, parietal of stomach 428
Charcoal and phenolphthalein 337
Chaulmoogra oil 928
Chemotherapy 126
Chenopodium, oil of 771
Chinofon 568
Chloride, in duodenum 864
Chlorides, blood 881
Cholangiography 870
Cholecocho-duodenostomy 72
Cholecystectomy, symptoms after 75
Cholecystitis 74
acute 371
bile salt in 577
obstructive 445, 597
Cholecystography 796
Cholesterol 127
in arteriosclerosis 860
Chondroitin 289
Chorea 917
Cinchophen ulcer 822
Cirrhosis, of head of pancreas 683
portal 890
Clamp, lobectomy 804
Colitis 297
and ileitis 134
chronic ulcerative 56, 191
treatment 71
Frei tests and 667
irrigation 65
mucous 326
physiology of 73
ulcerative, skin in 19, 140, 740, 839
Colon, allergy in 181
bacteria in 397
diverticulosis 580
elbow deformity 344
in mental disease 528
mucosa of 108, 494
polyposis of 509
prolapse of 280
redundant 76
Colostomy 282
palliative 612, 810
Coma, diabetic 179
Constipation 65, 586
Constitution, and peptic ulcer 90, 92
and ulcer 474
Cord, degeneration of 215
Corpus, luteum and gastric secretion 482
Cryptitis, anal 188
Cysts 191
enteric 200
mesenteric 146
pilonidal 500
Death, cause of 351
Deficiency, vitamin B 324
vitamin, in diets 759
Deformity, of colon 344
Dementia precox 528
Denervation of sphincter 167
Dermagraphic time 90, 92
Detoxication 570
Diabetes, 490 cases 178
diet for 759
Diagnosis, bacteriophage in 673
jaundice 315
